(Dated:)

This paper addresses the problem of certifying the performance of a precision flexure-base mechanism design with respect to the given constraints. Due to the stringent requirements associated with flexure-based precision mechanisms, it is necessary to be able to evaluate and certify the performance at the design stage, taking into account the possible sources of errors: such as fabrication tolerances and the modeling inaccuracies in flexure joints. An interval-based method is proposed to certify whether various constraints are satisfied for all points within a required workspace. Unlike the finite-element methods that are commonly used today to evaluate a design, where material properties are used for evaluation on point-to-point sampling basis, the proposed technique offers a wide range of versatility in the design criteria to be evaluated and the results are true for all continuous values within the certified range of the workspace. This paper takes a pedagogical approach in presenting the interval-based methodologies and the implementation on a planar 3RRR parallel flexure-based manipulator.

PACS numbers:

I. INTRODUCTION

Flexure jointed mechanisms [1] have been widely utilised in precision positioning and manipulation devices [2], such as for pattern alignment in semiconductor fabrication, micro-assembly, micro-surgery, and various scanning microscopy techniques [3, 4], as well as for the design of micro-scaled mechanisms, such as micro grippers and micro transducers, especially as the scale involved does not allow the use of conventional roller-bearing type of joints.

Due to the high precision nature of the applications, there is a stringent demand on the performance of the manipulator. Currently, finite element methods are often employed to simulate the performance of the mechanism design, however this is limited in the types of criteria and does not allow a guaranteed solution. It also tends to be computationally intensive. Topological information of the mechanism is often not considered and evaluation of the performance is on point sampling basis. It is therefore difficult to guarantee that the manipulator satisfies the required constraints for all poses of its required workspace. Furthermore, there is also the issue of modeling inaccuracies in flexure mechanisms. Generally, when constructing the kinematic model of a flexure-joint mechanism, an ideal model is used for the flexure joint, for example, a revolute flexure joint is modeled as an ideal revolute joint. The deformation of the joint during deflection, however, produces residual translational motion. An attempt to take into account this residual motion was given in [5], where a revolute flexure joint was represented as a pair of revolute and prismatic joints. However, an accurate model for such parasitic motion is complex to obtain.

In this paper, an interval-based method is proposed to evaluate the various constraints and to certify whether or not these constraints are satisfied within the desired workspace of the flexure-based manipulator. This would allow a designer to verify that various constraints, such as the reachable range of motion and the required motion resolutions, are achieved with the specific design. Furthermore, various uncertainties, including the inaccuracies of joint modeling and fabrication tolerances, can be accommodated as a bounded variations in the kinematic parameters. When a given workspace is certified as having satisfied all the constraints, the certification is valid for all the continuous values within the bounds, even in the face of the above-mentioned uncertainties.

The work on obtaining the workspace of a manipulator has been presented in the past through geometrical approach [6, 7] and screw theory [8]. These methods define the boundaries of the manipulators geometrically and provides algebraic expressions to the boundary curves. The method presented in this paper obtains the same results as the analysis presented in [6] - where the workspace boundary of a specific manipulator was de-
scribed through a geometric approach. The interval analysis method proposed in this paper has the advantages of being more general, easily adapted to other kinematic topologies, capable of handling any types of constraints expressed as mathematical equalities / inequalities, as well as uncertainties in parameters and rounding error. The geometric approaches require complex mathematical derivation prior to numerical computation to obtain the workspace boundaries, specific to the mechanism, however it is computationally more efficient. It also calculates only the workspace boundary given the topology, but it is not able to take into account joint limits or any other types of constraints, such as motion resolution and singularities.

This paper presents a complete workspace evaluation technique for a flexure mechanism. A brief introduction of flexure mechanisms and the overall constraint satisfaction method through interval analysis are presented in Section 2 and 3, respectively. The implementation of the algorithm, through constraints commonly required for precision flexure mechanism, is presented in Section 4, illustrated through the example of a 3RRR planar flexure-mechanism. The paper discusses the results of the implementation through the direct implementation of the described algorithm, as well as through the more advanced interval techniques available to achieve a better (sharper) result. Concepts of the advanced techniques are elaborated, with proper references given to cover the details of these techniques. A note on the numerical efficiency of the algorithm is presented and conclusions are drawn in Section 5.

II. FLEXURE MECHANISMS

Flexure mechanism [1] is formed by significantly reducing the cross sectional area of a member at a particular point so that deflection through elastic deformation can be induced about that point while treating the rest of the member as an ideal rigid body. As such, flexure joints do not suffer from any nonlinearities commonly associated with conventional joints such as friction, stiction, and backlash. They do, however, provide a much smaller range of displacement compared to conventional joints. Hence, they are suitable for precision manipulation.

The range of deflection that a flexure joint can undergo depends on the shear modulus of material and the design of the joint. This range of deflection provides a natural bound to the joint displacement variables which then acts as a constraint in determining the achievable workspace of the end-effector through interval analysis method. Due to the high precision nature of the applications, flexure-based mechanisms have a strict fabrication tolerance and therefore high cost of fabrication. This is true for the larger flexure mechanisms for micro/nano precision manipulation as well as for the micro-scaled mechanisms. In this paper, we focus on the notch type joints [1], which (in ideal case) produce a one DOF revolute joint motion, without loss of generality in the algorithm presented for performance evaluation and the guarantee of constraint satisfaction. This type of flexure joints, as demonstrated in [5], exhibits a residual translational motion in addition to the ideal revolute displacement. This motion is complex to model accurately and it affects the accuracy of the forward and inverse kinematics of the mechanism. Other types of potential errors in the fabrication and assembly of a flexure jointed mechanism are outlined in [9].

III. INTERVAL-BASED KINEMATICS

The goal of the algorithm is to solve the kinematics of a given mechanism to obtain the range of end-effector workspace such that the required constraints are satisfied. In this paper, $\mathbf{x}$ is defined as a vector containing the task space variables $(x, y, \theta)^T$, $\mathbf{h}$ is a vector containing the design parameters of the mechanism (such as link lengths), and $C(\mathbf{x}, \mathbf{h}) \leq 0$ is the mathematical inequality representing the constraints to be satisfied. The problem can therefore be formulated such that:

$$\forall \mathbf{x} \in [\mathbf{x}_L, \mathbf{x}_U], \forall \mathbf{h} \in [\mathbf{h}_L, \mathbf{h}_U]: \ C(\mathbf{x}, \mathbf{h}) \leq 0$$

where $\mathbf{x}_L$, $\mathbf{x}_U$ and $\mathbf{h}_L$, $\mathbf{h}_U$ are the lower and upper bounds of the range of values in $\mathbf{x}$ and $\mathbf{h}$, respectively.

As an overview, the interval analysis method involves several main components (1) interval extension or evaluation of functions, (2) constraint satisfaction: testing against the constraints and obtaining the inner, outer, or boundary boxes, (3) filtering, to enforce the consistency of various variables in the constraints, and (4) branch-and-bound loop within which the other components are carried out.

The goal of the strategy is to certify whether a particular range of workspace $[\mathbf{x}_L, \mathbf{x}_U]$ and design parameters $[\mathbf{h}_L, \mathbf{h}_U]$ yield either inner or outer boxes to constraint $C(\mathbf{x}, \mathbf{h})$. If the range of the solution is too wide, often it is not possible to obtain a decision, in which case, filtering and branch-and-bound process are utilised. Filtering process sharpens the result of constraint evaluation while the branch-and-bound process splits the variables into smaller ranges and evaluates the constraints as a function of each subset of variable individually. The details of the components are presented in the following sub-sections.

A. Interval Extension

The interval extension of variable $x$ is defined as $X$, bounded within its lower and upper bounds $[\underline{x}, \overline{x}]$, where $\underline{x} \leq x \leq \overline{x}$. The width of the range is defined as $\overline{x} - \underline{x}$. The interval extension of a function is the evaluation of a function with interval variables. Types of function interval extension are natural extension [10] and Taylor-form extension [11, 12]. Natural extension is where real variables in a function are substituted by the equivalent
interval variables. Hence, in this case:

\[ \forall x \in X, \ f(x) \in F(X); \]  

\[ \forall x \in X, \ f(x) \in F(X); \]  

is the natural extension of \( f(x) \). Taylor form extension utilises the partial derivative of the function \( f(x) \). Interval methods can be used conveniently to bound the remainder of truncated Taylor series. In this paper, the natural extension was utilised.

During the interval evaluation of a function, as numerical values are substituted into the function, the relationship between various variables are lost. Overestimation occurs when the same variables appear more than once within the function and they are regarded as independent variables. The evaluation of a function where all variables involved appear only once is sharp (within rounding errors), meaning it is bounded within the smallest possible “box”. For example, let \( X = [1, 2] \) and \( Y = [3, 6] \). Evaluating \( F(X, Y) = X + Y = [4, 8] \) would therefore be sharp. However, evaluating \( G(X, Y) = X - X = [1, 2] - [1, 2] \) results in \([-1, 1]\) and is not equal to zero, although we know it should. This is because the two variables \( X \) are taken as being independent and not as the same variable. The effect of overestimation can be seen further in later subsections.

### B. Types of Solutions

After the evaluation, it is necessary to test whether a required constraint is satisfied in the system. In our problem, it is desired to verify whether the required performance constraint \( C(X, H) \) of the mechanism is true for the set of given workspace pose (variables) of interest \((x \in X)\) and mechanism parameters \((h \in H)\), as presented in (1). There are two types of constraints to be evaluated:

- **Inequality Constraint.** When this is the case, the evaluated function \( C(x, h) \) is said to satisfy the required constraints when:

  \[ \forall x \in X, \forall h \in H : \ C_R \leq C(X, H) \leq \overline{C}_R ; \]  

  \[ \forall x \in X, \forall h \in H : \ C_R \leq C(X, H) \leq \overline{C}_R ; \]  

  where \( C_R \) and \( \overline{C}_R \) are the lower and upper bounds of the requirements for the constraints. This is also termed the inner solution or the inner box of the constraint. The outer box is obtained when \( \forall x \in X, \forall h \in H : \ (C(X, H) \leq C_R) \text{ or } (C_R \leq C(X, H)) \). Boundary solution or a boundary box is found when it cannot be decided whether \((x, h)\) is an inner or outer box of the constraint.

- **Equality Constraint.** When it is desired to obtain the solution of

  \[ \forall x \in X, \forall h \in H : \ C(X, H) = 0, \]  

  then it is comparatively easier to obtain the outer box of the constraint. The outer box is obtained by solving for: \( \forall x \in X, \forall h \in H : \ 0 \notin C(X, H) \). When \( 0 \in C(X, H) \), then it is only possible to deduce that a solution exist within \((X, H)\), however it is not enough to define inner boxes.

### C. Filtering

Filtering process enforces the consistency in the variables involved in the evaluation of an interval function / constraint. These techniques originated from the constraint programming field of study. It involves removing the segments in the interval variables involved that do not hold within the constraints. In this paper, the filtering process is used to reduce the effect of overestimation on the interval extensions of functions.

Overestimation of an interval function makes it difficult to decide whether or not a set of interval variables satisfies the given constraints. Consistency filtering is therefore required to sharpen the resulting boxes. The process utilises the additional information contained within the mathematical equations or the physical constraints. In the case of mathematical equations, different ways of expressing the same equations yields different bounds to the interval evaluation, due to varying degrees of overestimation. This is utilised in the filtering process by ensuring the consistency of the solutions throughout the various ways of expressing the same equation. In the case of physical constraints, additional information obtained from the physical or mechanical properties of the system are utilised to obtain a consistent solution. In this paper, for example, a parallel mechanism is constructed out of several articulation chains that connect the base platform to a common moving platform. Forward kinematics of each chain to the common end-effector, for example, provides additional constraints that can be used to reduce the effect of overestimation.

In solving for the consistency of an equation, the concept is to ensure that the interval extension of a function produces a solution that is consistent with the given constraint. For example, let \( f(x, y) = x^2 - x y + 2 y = 0 \) be the specified constraint and that the initial estimates of the interval extension of variables \( x \) and \( y \) be \( X = [3, 9] \) and \( Y = [1, 4] \), respectively. If the interval extension of function \( f(x, y) \) is evaluated, we obtain \( F(X, Y) = [9, 81] - [3, 36] + [2, 8] = [-25, 86] \). However, to ensure the consistency in the constraint, it is possible to rewrite the equality such that:

\[ X^2 = Y(X - 2) = [1, 28] \]  

\[ X = [-5.3, 5.3]. \]  

Taking the intersection of (5) and the initial estimate of \( X \) to obtain \( X \in [-5.3, 5.3] \cap [3, 9] = [3, 5.3]. \) Similarly, this can be performed on variable \( Y \) with the improved estimate of \( X \). This can be iterated until such time that the improvement in the sharpness of the bounds is no longer worth the computational effort.
The procedure described above is termed 2B consistency [13, 14]. Other filtering techniques are available such as 3B and interval Newton [10, 11, 15, 16].

D. Branch-and-Bound

It is often difficult to conclude whether a given box constitute an inner or outer box when it is evaluated as a function of interval variables with large width. While filtering process contracts the box and attempts to obtain a sharp solution, it can only return the sharpest box that would contain the solution. Within the box, the solution often occupies only a portion of the bounded space. The branch-and-bound strategy is therefore utilised to automate the solution search of the algorithm such that a better definition of the solution may be found.

The branch-and-bound algorithm searches for the solution by evaluating a box and deciding whether it yields an inner, outer, or boundary box. If it yields a boundary box, then the box is split (bisected) and each of the bisected boxes is iteratively evaluated following the same process. The bisection process is iteratively performed until an inner or outer box is found, or until a threshold dimension of the variable boxes $\epsilon$ is reached. Boxes that remains as boundary solution at this point will form the boundary solutions of the system. In this paper, to evaluate the performance of a mechanism within the specified workspace $X$ with a specific mechanism parameters $H$, bisection is performed on the $M$ dimensional interval box $X$ where $M$ is the number of the task space pose (workspace) variables. In the case of our planar parallel mechanism, $M = 3$ and is made up of 2 translation and one orientation degrees of freedom. Bisection process is performed across all the pose variables in different order, depending on the bisection algorithms. Several possible bisection algorithms are available [17]. The simpler approaches are the round robin (bisection of variables by turn) and the largest first (bisection of the variables with the largest width first). Both the strategies above suffer from the simplistic approach. A more intelligent bisection algorithm was proposed [18] by utilising the derivative of the system. This algorithm defines the smear function of the system and aims to identify the dominant variable that affects the system the most at that iteration. The most dominant variable is then selected for bisection. This approach is effective as it attacks the problem where bisection would yield the most effect. However, it has a drawback that it may continuously bisect specific dominant variables until $\epsilon$ is reached. This is amended by defining a minimum allowable threshold in the ratio of the width of a variable to its original width, beyond which bisection turn is handed over to the next dominant variable.

E. Summary of Algorithm

The proposed algorithm is summarised in Table I. Constraint function $C(X, H)$ can contain a single design constraint to be evaluated, expressed as mathematical equalities or inequalities, or a list of constraints. In the case where there are multiple constraints to be evaluated, an inner box is obtained only if $X_i$ satisfy all the constraints (forms an inner box to all constraints) and an outer box is obtained if $X_i$ fails to satisfy any of the constraint. The resulting solutions are contained in lists (see Table I): list $L_{IN}$ contains the inner solutions that satisfy all the constraints, while $L_{OUT}$ contains outer boxes, i.e. when a box fails to satisfy any one of the constraints in $C$. The boundary boxes are given in list $L_B$.

The variable $X$ contains the end-effector workspace description, i.e. position $(x, y)$ and orientation ($\theta$) for the planar case considered in this paper (3 DOF planar mechanism). However, a 6DOF mechanism will have the bisection process performed across the six-dimensional box describing the workspace (as can be deduced from the algorithm in Table I). This would increase the computational cost of the algorithm. It should be noted, however, that the complexity in formulating and using the algorithm does not change a great deal. This is one of the advantages of the proposed algorithm, i.e. its versatility - often as a trade-off to computational cost, when compared to a more problem-specific algorithm. As long as constraints are expressed mathematically, most of the work will be carried out by the numerical computation. In contrast to other methodologies, such as the geometric approach, as mentioned in the introduction, where mathematical derivation is very much mechanism specific and a 6DOF mechanism will be much harder to solve than a 3DOF.

IV. INTERVAL ANALYSIS: 3RRR PARALLEL FLEXURE MECHANISM

In this section, the workspace verification problem of a 3RRR planar flexure mechanism with respect to the various constraints relevant to the functionality of a precision manipulator is solved using the interval based techniques presented in Section III. The problem is to evaluate the performance of the manipulator defined by the design parameters $H$, with respect to design constraints $C(X, H)$, at the required workspace pose $X$ and to certify whether $X$ is a solution to the performance constraints.

The performance criteria of the planar manipulator that are presented to help illustrate the algorithm in this paper are (1) the amount of workspace reachable through the allowable deflection of the flexure joints, (2) singularity free workspace, and (3) the workspace that yields the required motion resolution given the resolution of the joint space. The 3RRR planar parallel mechanism, with the definitions of the variables and frame assignments, is given in Fig. 1.
TABLE I: Summary of algorithm for workspace constraint analysis with interval analysis.

1 Initialise empty lists \( L_{IN}, L_{OUT} \), and \( L_B \).
2 Initialise list \( L \) containing initial task space intervals (boxes) to be analysed.
3 While \( L \) not empty
(a) Extract manipulator pose \( X_i \) from list \( L \).
(b) Evaluate constraints \( C(X, H) \) against the required performance \( C_{em}, T_{em} \).
(c) Test \( C(X, H) \) against the required performance \( C_{em}, T_{em} \).
(d) Filtering process is carried out if necessary.
(e) Return whether \( X \) constitutes an inner, outer, or boundary box.
(f) Case result is inner, outer, or boundary box:
   (a) Case 1: The solution lies within the ALL constraints \( C(X, H) \).
      Remove \( X_i \) from \( L \) and add to list \( L_{IN} \).
   (b) Case 2: The solution lies outside ANY of the constraints in \( C(X, H) \).
      Remove \( X_i \) from \( L \) and add to list \( L_{OUT} \).
   (c) Case 3: If \( X_i \) is a boundary solution
      \( (\text{dimension of box } X_i) > \epsilon \).
      Bisect \( X_i \) into \( X_{i1} \) and \( X_{i2} \) and add to list \( L \).
      Else if \( \epsilon \) has been reached.
      Remove \( X_i \) from \( L \) and add to list \( L_B \).
4 End While

FIG. 1: A 3RRR planar parallel mechanism

The planar workspace of the manipulator is defined as \( X = \{p_e = \{x_e, y_e, \theta\}^T\} \), which comprise the position and the orientation of the end-effector, respectively (see Fig. 1). For simplicity, the task space variable is always expressed with respect to the base frame \( O \), therefore reference to the frame is omitted in this paper, i.e. the task space variable will be written simply as \( p_e = \{x_e, y_e, \theta\} \). Joint space variables are the \( (\alpha_i, \beta_i, \gamma_i) \), where \( i = 1, 2, 3 \) represents each of the three serial chains connecting the base and moving platform. It is assumed that only joints \( \alpha_1, \alpha_2, \alpha_3 \) are actuated (\( RRR \) chains) and displacement sensor feedbacks are only available on these joints. This is used as the case study to illustrate the algorithm, although it is possible in precision mechanisms to install displacement sensors to measure motion directly at the end-effector. Several planar parallel micro-positioning mechanisms in the literature are designed in this topology [5, 19].

The position vectors of points \( B_1, B_2, B_3 \) with respect to base points \( O_1, O_2, O_3 \) are defined as \( p_1, p_2, p_3 \), respectively (where \( p_i = \{x_i, y_i\}^T \)). These points move with the end-effector, hence their positions are given by the position of the end-effector \( \{x_e, y_e\} \), the displacement caused by the orientation of the end-effector \( \theta \) due to the offset distance \( d = \{d_1, d_2, d_3\}^T \). With respect to the global origin \( O \), these vectors are defined as \( \{p_1, p_2, p_3\} \). The position vectors \( p_1, p_2, p_3 \) are obtained through:

\[
p_i = O p_i - O;
\]

\[
= p_e + R_Z(\theta + \angle d_i), \begin{bmatrix} 0 \\ 0 \\ d \end{bmatrix} - O;
\]

where \( d \) is the length of vectors \( d_1, d_2, d_3 \), which are assumed to be of equal length, \( \{\angle d_1, \angle d_2, \angle d_3\} = (\pi/6, -\pi/6, \pi/2) \) are the headings of vectors \( d_1, d_2, d_3 \) when the flexure joints are at rest.

The manipulator design is used as an example in the following sub-sections to better illustrate the algorithm proposed. The various link lengths of the selected 3RRR planar parallel mechanism are summarised in Table II. The pose of the end-effector when the 3RRR mechanism is symmetrical is defined as \( p_{sem} = \{x_{sem}, y_{sem}, \theta_{sem}\} \), which is also the pose when the flexure joints are at rest, i.e. when they undergo zero deflections. The algorithm was implemented in C++ with ALIAS library developed upon BIAS/Profil platform within the COPRIN project [20].

### A. Workspace by Joint Limits

It is imperative that the joint displacement in a flexure joint takes place only within the linear deformation region of the member. This depends primarily on the shear

modulus of the material and the design of the joint. After taking into account the safety margin, the selected values of maximum allowable joint deflection used in the interval analysis of the flexure mechanism workspace should constitute a bound for which the joints behave linearly within the elastic region.

To obtain the joint displacement of the mechanism for a given end-effector pose, inverse kinematics is carried out on the desired end-effector workspace (X), with the given interval link length parameters (H). The inverse kinematics of planar parallel mechanisms is often discussed in the literature [21] [22]. Generally, inverse kinematic solution can be obtained by first calculating the angle β_i, which has two possible solutions within [0, 2π]. Choosing one of the two possible solutions for each β_i, the joint displacement of angle α_i can be obtained. Obtaining the inverse cosine or inverse sine of an interval variable does not uniquely define the solution angle as these trigonometric functions are periodic. To overcome this problem, the constraints on the allowable joint deflection are expressed as the limits on the sine and cosine of the joint limit angles. For a flexure jointed mechanism, however, the unique solution to β_i can be determined (whether it is the elbow up or elbow down solution), due to the limited motion of the mechanism. The closed-form solution of the inverse kinematics is therefore given as follows:

\[
\begin{align*}
\cos(\beta_i) &= \frac{x^2+y^2-(r^2+l^2)}{2rl_x}, \\
\cos(\alpha_i) &= \frac{x(y_1l_2\cos(\beta_i)+y_1l_1\sin(\beta_i))}{x^2+y^2}, \\
\sin(\alpha_i) &= \frac{-x_1l_1\sin(\beta_i)+y_1l_2\cos(\beta_i)}{x^2+y^2}.
\end{align*}
\]

(7)

Although angles γ_i are not usually considered theoretically in the inverse kinematics of a 3RRR planar parallel mechanism, it is important in practical cases to take the limits of these joints into account - such as to avoid collisions among the links of the mechanism. In the case of flexure jointed mechanisms, it is also necessary to impose a joint limit constraint on these joints, as they are also flexure joints. From Fig. 1, it can be observed that

\[
\alpha_i + \beta_i + \gamma_i = \angle(-\mathbf{d}_i).
\]

(8)

1. Constraint Definition

The interval extension of end-effector workspace variables \(\mathbf{p}_e = (x_e, y_e, \theta_e)^T\) were utilised to describe the desired range of the workspace X. The interval variables for the link lengths (H), however, were used to express the fabrication tolerances and other un-modeled sources of errors. With these variables defined, the constraint for the workspace as defined by the allowable joint deflections. As trigonometric functions are periodic, the joint limits are expressed as the upper and lower bounds of their trigonometric functions (cosine and sines). The joint displacement limit for a joint \(q_i\) can therefore be expressed as:

\[
\cos(q_i) \in [\cos(q), \cos(q)] \text{ AND } \sin(q_i) \in [\sin(q), \sin(q)].
\]

(9)

A box of solution \(X_i\) is an inner solution when all of the joint limit constraints are satisfied. The workspace described by the inner box is reachable by the end-effector of the mechanism, given the allowable flexure joint deflection. A box \(X_i\) is an outer box if any of the interval inverse kinematic solutions falls within the complement of (9).

2. Results and Discussion: Workspace by Flexure Joint Limit

In this example, the allowable joint deflection was set at ±3°. The workspace to be evaluated is selected as a motion range of ±2.5 mm in x and y direction \((x_e = y_e = 2.5\text{mm})\) and ±17.5 milli radian \((\theta_e = 1^\circ)\) for orientation, about \((x_{em}, y_{em}, \theta_{em})^T\), respectively.

![FIG. 2: Workspace of the 3RRR planar parallel mechanism, under joint limit constraint (a) without considering fabrication tolerances and (b) assuming ±50µm tolerance on link length r and l, at constant \(\theta = \theta_m = -10.3^\circ\).](image-url)
uncertainty involved in the interval calculation of the inverse kinematic problem. The following set of physical constraints, essentially forming the direct kinematics of vector $p_i$, were utilised as additional constraints in the enforcing the consistency of the inverse kinematic solutions:

$$
C_i(X, H) = R_i \cos(\alpha_i) + L_i \cos(\alpha_i + \beta_i) - X_i = 0;
$$

$$
C_2(X, H) = R_i \sin(\alpha_i) + L_i \sin(\alpha_i + \beta_i) - Y_i = 0;
$$

$$
C_3(X, H) = (\cos(\alpha_i))^2 + (\sin(\alpha_i))^2 - 1 = 0;
$$

A 2B/3B consistency filtering was implemented and the improvement on the inner solution is shown in Fig. 2(a). This two dimensional figure display the inner and outer boxes of the manipulator workspace when the flexure-joint limits are imposed, after consistency filtering. It is taken at constant $\theta = \theta_m = -10.3^\circ$. The effectiveness of the filtering technique can be clearly seen in the ability of the algorithm in admitting inner solutions.

The result in Fig. 2(a) was produced by assuming zero uncertainties in the fabrication tolerances and no uncertainties in the flexure joint modeling. In this case, interval variable $R_i$ and $L_i$ were defined as degenerate intervals, such that they have the same values of the lower and upper bounds (zero interval width). As explained in Section II and presented in [5], the un-modelled kinematics of a notch type revolute flexure joint manifest itself in an additional amount of translational motion. This can be modelled as additional uncertainties in the link lengths $L_i$ and $R_i$. This un-modelled degree of freedom is complex to model and comparatively small in magnitude. In our technique, the bounds of the error estimate are used to account for the additional translation in the absence of a complex and accurate model. Additional uncertainties due to fabrication tolerances are also added to the interval variables $L_i$ and $R_i$. To include such uncertainties into the evaluation process, these bounds of uncertainties are added to the link lengths $L_i$ and $R_i$.

In our example, the additional uncertainties due to un-modelled kinematics and the flexure fabrication tolerance are defined as being bounded within $\pm 50 \mu m$ for each link length $r_i$ and $\ell_i$. The resulting workspace within the limits of allowable flexure joint deflection, is shown in Figure 2(b) as comparison. As expected, there is a larger area of boundary solutions compared to when fabrication tolerances and modelling errors were not considered. However, the inner solutions exist such that the represented workspace range is certified to be within the required constraints, with the fabrication tolerances and the uncertainties in kinematic model taken into account. It is therefore demonstrated that various uncertainties, including fabrication limitations, can be included in the calculation during the design process to guarantee that the performance of the resulting mechanism is within the specified requirements.

Figure 3 demonstrates the workspace of the mechanism bounded by the allowable joint deflection for a range of orientation $\Theta$, represented by the vertical-axis of the plot. The range of interval $\Theta$ is $\pm 17.5 mrad$.

![FIG. 3: The inner solution admitted into the workspace of the 3RRR planar parallel flexure mechanism. The orientation range is $\theta^2 = \theta_m \pm 17.5 mrad$.](image)

### B. Singularity

It is also desired to evaluate the workspace of the mechanism to certify that the operational region is free of singularity. The constraint, in this case, is the function defining the loci of singularity. The singularity free region is the end-effector workspace that can be guaranteed to contain no solution to the constraint. For simple mechanisms, it is possible to obtain the symbolic expression of the determinant of the Jacobian matrices. However, obtaining symbolic expression of singularity for more complex mechanisms with higher degrees of freedom may not be practical. An efficient method was proposed in [23] to evaluate the regularity of the interval Jacobian matrix numerically. This method is used in this paper to obtain the non-singular workspace of the mechanism.

The differential kinematic relationships can be obtained from [21] as

$$
[f^T, f^T_i d^T_i] \begin{bmatrix} \dot{p} \\ \omega \end{bmatrix} = r_i f_i^T \begin{bmatrix} -\sin(\alpha_i) \\ \cos(\alpha_i) \end{bmatrix} \dot{\alpha},
$$

where $f_i^T$ is the unit vector in the direction of the reciprocal screws passing through the revolute joints at points A and B:

$$
f_i^T = \frac{1}{l_i} \begin{bmatrix} x_i - r_i \cos(\alpha_i) \\ y_i - r_i \sin(\alpha_i) \end{bmatrix},
$$

$d_i^T$ is the vector perpendicular to $d_i$, or $d_i^T = (-d_{iy}, d_{ix})^T$, and $\dot{\alpha}$ is the vector containing the rate of the actuated joints $(\dot{\alpha}_1, \dot{\alpha}_2, \dot{\alpha}_3)$, as defined in Fig. 1. The overall differential kinematics of the mechanism can be described by:

$$
J_1 \dot{x}_e = J_2 \dot{\alpha},
$$

where $\dot{\alpha} = (p^T_i, \omega)^T = (\dot{x}_e, \dot{y}_e, \dot{\theta})^T$ and $J_1, J_2$ are the $3 \times 3$ Jacobian matrices, with each row representing the
relationship (11) for individual leg $i$. Note that $J_2$ is a diagonal matrix.

1. Constraint Definition

The constraint for singular workspace of the mechanism is defined as:

$$
C_1(X, H) = \det(J)_1 = 0;
C_2(X, H) = \det(J)_2 = 0;
$$

(14)

It is possible to guarantee that a specific box in the workspace does not contain singularity by solving for the workspace such that:

$$\{\forall x \in X, \forall h \in H, (0 \notin C_1(X, H) \land 0 \notin C_2(X, H)}\}
$$

(15)

2. Results and Discussion: Singularity-free workspace

Singularity associated with a rank deficient $J_1$ and $J_2$ are the internal and the boundary singularities of the mechanism, respectively. To demonstrate the interesting features in this evaluation, the singularity analysis is performed considering the entire workspace the 3RRR mechanism, independent of the joint displacement limits. The resulting loci of singular-free configurations, obtained by the direct evaluation of constraint (15).

For the clarity of further analysis, the singularity-free workspace for constant orientation is presented as 2 dimensional plots in Fig.4(a), taken at $\theta = 40^\circ$. It can be seen that in this example, direct evaluation does not produce a very sharp result even after the consistency filtering process, leaving a large region of boundary solutions. As highlighted earlier, it is difficult to decide on the solutions of equality constraint. To improve the sharpness of the solution, an advanced numerical regularity test, that has been implemented on the ALIAS library [23] was then utilised to enhance the performance of the algorithm. This regularity test utilises

algorithm component 1: the Rohn consistency test to determine the interval matrices that are regular. The Rohn consistency test states that for an interval matrix $I$, if a well defined set of scalar matrices derived from $I$ have determinants of the same sign, then there is no singular matrix in $I$. This is a powerful test to certify the outer box of the equality, i.e. to certify that a box of workspace does not contain any singularity, i.e. $0 \notin C(X, H)$.

algorithm component 2: a matrix regularity test through the sign of the matrix determinant (as proposed in [23]) to certify that a matrix contains singularity. It is carried out by sampling points within a given box and comparing the signs of the determinants for these points. If there exists any point

in the interval box that displays a different sign of determinant from other points, then singularity exists within the interval box. This provides a strong tool to certify the existence of a singularity within an interval matrix.

Combined, the two techniques provide an effective tool to evaluate the singularity of mechanisms.

Another point to note is if this test concludes that a solution to the equality exists in the interval box $(X, H)$, it does not mean the entire box is singular (as singularity is a point). Therefore, the interval box should not be immediately assigned as singular but as a boundary solution to be bisected further to localise the singularity loci. It is therefore possible to narrow down the boundary boxes to the size of $\epsilon$ (the threshold of the smallest dimension of workspace region where bisection process is terminated). This method identifies singularity numerically down to the threshold dimension $\epsilon$. The large improvement on the sharpness of the solution, provided by this approach, over the direct evaluation method is shown in Fig. 4(b), where the loci of singular configurations are marked in red solid line for a clearer view.

It should be noted that evaluating the singularity-free constraint over the end-effector workspace within the allowable joint displacement limits (Section IV A) yields no singularity. Referring to Fig.4, the centre portion of the
workspace is where the determinant of the Jacobian matrix is negative, while the three portion along the edges are of positive determinant. It is important that operational workspace and the motion path planning of the end-effector do not cross between a positive and negative determinant regions. This demonstrates the ease with which interval analysis techniques can be adapted to verifying a singularity-free path planning problem.

It might also be of interest to note that an optional technique exists to trace the loci of singularity once one singular point is found in the workspace. Once a singularity point is found, the continuation method [24, 25] can be employed to trace and identify the loci of singular configurations. This may provide a faster solving algorithm.

C. Task Space Motion Resolution

Another important characteristic in flexure mechanism is the task space motion resolution. As these mechanisms are generally employed for precision manipulation, the resolution of the smallest step possible in the motion of the end-effector is often an important performance criterion. Generally, it is possible to directly establish the bounds of joint space motion resolutions from the specifications of the sensors and actuators used. Incremental step size in the task space can therefore be calculated by the differential kinematic relationship with the incremental step size in joint space displacement.

\[ \mathbf{J}_1 \Delta \mathbf{x}_c = \mathbf{J}_2 \Delta \mathbf{q}, \]

where \( \Delta \mathbf{q} \) is the incremental step in joint space. Since a 3RRR mechanism is considered in our case, then only the three base joints are actuated. It can be assumed that only these active joints are equipped with displacement sensors. Hence, \( \Delta \mathbf{q} = (\delta \alpha_1, \delta \alpha_2, \delta \alpha_3)^T \). It is then required to solve for \( \Delta \mathbf{x}_c \) in the linear equation (16). This is done in this paper using Gaussian method [16]. Several interval arithmetics packages have Gaussian solving function ready, hence users do not need to code this function from scratch.

1. Constraint Definition

The constraint to be satisfied is therefore defined as:

\[ |\Delta \mathbf{X}_c| \leq \Delta \mathbf{X}_{max}; \]

where \( \Delta \mathbf{X}_c \) is the interval extension of vector \( \mathbf{x}_c \) as defined in (16) and \( \Delta \mathbf{X}_{max} \) is the largest end-effector motion resolution required for the task. Inner boxes are obtained when the specified workspace satisfies (17) and outer boxes when \( |\Delta \mathbf{X}_c| > \Delta \mathbf{X}_{max} \).

For this example, it is given that joint space displacement resolution is bounded within 0.06 mrad. The desired resolution (\( \Delta \mathbf{X}_{max} \)) for the task space translational motion and orientation are set at 0.5\( \mu \text{m} \) and 0.5mrad, respectively.

D. Overall Available Workspace

When a Gaussian elimination technique was utilized, the algorithm yielded no inner solution to the constraints. Preconditioning process [11] was performed to improve the sharpness of the solution. Preconditioning was applied by pre-multiplying both sides of the equation with matrix \( \mathbf{M} \), where \( \mathbf{M} = (\text{mid} (\mathbf{J}_1))^{-1} \), and where \( \text{mid}(\mathbf{J}_1) \) is the matrix containing the mid values of the elements of the interval matrix \( \mathbf{J}_1 \). When (16)-(17) is evaluated for the workspace of our 3RRR planar parallel manipulator, the workspace that satisfies the required motion resolution is given in Fig. 5(a). The solution was obtained through a variation of the Gaussian technique, named \text{Hansen-Blek} solving algorithm [26–28], which is numerically pre-conditioned.

Further improvement can be obtained through \text{symbolic preconditioning}, as proposed in [23]. It has been shown to be effective in complex systems to improve the sharpness of the solutions. This approach is possible when symbolic expressions of the linear system of equations is given. The idea is to minimise symbolically the number of multiple occurrences of the variables in an interval function. This method is performed by evaluating matrix \( \mathbf{M} \) but keeping \( \mathbf{J}_1 \) symbolic. Pre-multiplying the system with \( \mathbf{M} \) and keeping \( \mathbf{J}_1 \) symbolic allows the elements of the resulting matrix to be rearranged symbolically to minimise the multiple occurrences of various interval variables, hence reducing the effect of dependency. Consistency filtering is also included in the algorithm to further sharpen the results. The improve-ment in the algorithm ability to admit inner solution is demonstrated in the amount of workspace that can be certified as the inner solution of the constraint dictated by the desired end-effector motion resolutions. This is shown in Fig. 5(b). The results in Fig. 5 were obtained with identical conditions, taken at constant \( \theta = \theta_m \), with the only differences being the algorithms for solving the linear equations: (a) the preconditioned \text{Hansen-Blek} algorithm, and (b) the symbolically pre-conditioned Gaussian elimination method.
obtain a sharp solution to decide whether or not an interval in the workspace satisfies the design requirements. If a bounded solution cannot be obtained, then it cannot be guaranteed that all the design constraints are satisfied. It is then necessary to alter the design or to relax some of the requirements.

In the usage of interval analysis, it is important to note that various constraints require different levels of computational resources. Computational load increases exponentially with every additional bisection in the algorithm. In implementing our algorithm, computationally cheap constraints were calculated first within each iteration and, whenever possible, used to eliminate boxes that do not satisfy the constraint before calculating the more computationally expensive constraints. These can then be housed in a nested heuristic structure where the computationally most expensive constraints are calculated only when every other (computationally cheaper) constraint has failed to produce an inner or outer box. If an inner or outer box is not obtained even after filtering, then bisection is performed.

In the case of flexure mechanism, the joint limit is generally the largest contributor in reducing the available workspace, as flexure joint workspace constitutes only a very small portion of the overall mechanism workspace. In our example, it can be seen that the workspace allowed by the joint deflection limit is situated well within the singularity free region with negative determinant. An example of the usable workspace that satisfies all the criteria (joint limit, singularity-free, and required motion resolution) is therefore given by Fig. 6. The figure shows the zoomed-in view of the workspace, located well within the singularity-free region at the centre of the manipulator workspace, with nominal orientation at \( \theta_m = -10.3^\circ \). The two most stringent constraints in this example were the joint limit and the end-effector motion resolution. The workspace allowed by the joint limit is reproduced in Fig. 6 (a), the workspace that produces an end-effector motion resolution of 0.5 \( \mu \text{m} \) (translation) and 0.5 \( \mu \text{rad} \) (orientation), given joint motion resolution (\( \delta \alpha_i \)) of 0.05 \( \mu \text{rad} \), is given in Fig. 6(b) and the resulting intersection, which is the workspace that satisfies all the given criteria, is given in Fig. 6(c).

To test a desired workspace \( X \), with a particular manipulator design and link lengths \( H \), the interval variables of the workspace are substituted directly into the algorithm and certified whether or not they form inner boxes of the constraints. This is the case when the entire desired workspace consists of only inner boxes to all the given constraints.

Implemented on Dual Core Intel 2.4GHz processors (4MB cache) with 1GB RAM, the algorithm took 15s to verify that the flexure mechanism workspace with a range of \( \pm 1 \text{mm} \) in translation and \( \pm 1^\circ \) in orientation from its zero deflection point \((x_m, y_m, \theta_m)\) is entirely contained within the inner solution of all the constraints (represented by 8728 inner boxes). This demonstrates the efficiency of the algorithm.

V. CONCLUSIONS

A technique to address workspace verification problem of a precision flexure-based mechanism is presented in this paper. The technique certifies whether or not the required workspace satisfies certain a set of performance criteria, taking into account the modelling and fabrication uncertainties. Performance features relevant to a flexure-based mechanism are presented and the efficient interval-based methods in evaluating and resolving the features were proposed, implemented, and discussed. Future work is aimed at extending the algorithm to a produce an efficient synthesis algorithm that would enable the determination of design parameters of a mechanism that satisfy a set of given constraints. This method would require not only the verification of constraint satisfaction for a set of nominal design parameters but also for a continuous range of possible design parameters.
