Abstract

It is well-known in the field of dynamical systems that entropy can be defined rigorously for completely deterministic open-loop systems. However, such definitions have found limited application in engineering, unlike Shannon’s statistical entropy. In this paper, it is shown that the problem of communication-limited stabilization is related to the concept of topological entropy, introduced by Adler et. al. as a measure of the information rate of a continuous map on a compact topological space. Using similar open cover techniques, the notion of topological feedback entropy (TFE) is defined in this paper and proposed as a measure of the inherent rate at which a map on a noncompact topological space with inputs generates stability information. It is then proven that a topological dynamical plant can be stabilized into a compact set if and only if the data rate in the feedback loop exceeds the TFE of the plant on the set. By taking appropriate limits in a metric space, the concept of local TFE (LTFE) is defined at fixed points of the plant, and it is shown that the plant is locally uniformly asymptotically stabilizable to a fixed point if and only if the data rate exceeds the plant LTFE at the fixed point. For continuously differentiable plants in Euclidean space, real Jordan forms and volume partitioning arguments are then used to demonstrate that LTFE is the sum of the base-2 logarithms of the unstable eigenvalues of the Jacobian at the fixed point.

Keywords: topological entropy; communication channels; stabilizability

1 Introduction

An important consequence of Shannon’s pioneering work on statistical information theory was the development of definitions of entropy for deterministic nonlinear dynamical systems,
by Kolmogorov and others. These notions provide a framework within which to rigorously discuss the information generation rate, in bits per second, of purely deterministic maps, either in measure-theoretic or topological terms. However their impact in communications has been somewhat limited, due to the widespread use in that field of statistical source models which are often more naturally analyzed in terms of Shannon entropy. In contrast, deterministic models are commonly used in control. Until recently though, there has been no real motivation to define the information rate in bits/s of a plant in a control system, since it has almost always been assumed that the available outputs of a plant can be transported to the controller with arbitrarily high digital precision.

However, in many developing application areas such as micro-electromechanical systems and decentralized tracking, this assumption no longer holds true. The resources available for communication between sensors and controllers in such areas can be severely limited, due to size or cost. This impinges directly on the feedback control performance that can be achieved, since it implies that the data received by various components is either out-of-date or poor in resolution, if not both. In these situations the communications and control issues are bound together and the analysis of one aspect cannot proceed without consideration of the other. There are many issues which need to be considered in order to fully capture the effects of a non-ideal digital communication channel on a control system, e.g. limited data rate, variable or stochastic delays, and transmission errors. In this paper we follow a line of inquiry begun in [9] and continued in [29, 2, 3, 12, 5, 22, 16, 17], amongst others, and focus on the problem of stabilization with a finite data rate.

Within this perimeter, a fundamental question is how to define the intrinsic rate $h$ at which a given plant generates “stability” information. One possibility is to simply define it as the infimum data rate needed to be able to stabilize the plant, and indeed expressions for the infimum rate are available both for noiseless [19, 26, 21, 2, 14, 13] and stochastic [20] linear systems. However, the weakness of this approach is that it ties the definition of information rate to the particular structure placed on the coding and control scheme. Despite different formulations and assumptions in all the papers just referred to, the same infimum rate was obtained which furthermore was determined only by the unstable, open-loop eigenvalues of the plant and was independent of all parameters of the coding and control scheme. This strongly suggests that it ought to be possible to define an intrinsic information rate for the plant in a manner which makes no reference to coder, decoder or controller structure. There is an analogy here with source coding [25, 7], which is concerned with determining the smallest data rate at which a stochastic source can be coded, transmitted and “reliably” decoded over a noiseless digital channel. There are different formulations and definitions of “reliability”, ranging from variable length codes with no errors to fixed-length block codes with arbitrarily small error rates. Nonetheless, in all cases the smallest possible data rate is equal to the Shannon entropy of the source, independent of external constructs.

This paper is divided into five sections, excluding this Introduction. In the next section, we briefly discuss the open cover techniques used by Adler et. al. in defining the topological entropy of a continuous map without inputs on a compact topological space. Motivated by the generality possible with such methods, we modify them to deal with plants on (possibly non-compact) topological spaces. This leads to the new concept of topological feedback en-
tropy (TFE), which we propose as a rigorous and completely general measure of the rate at which a plant generates initial state information under certain controllability-like constraints.

In the third section, we formulate the problem of controlling a topological dynamical systems with a finite feedback data rate, the basic objective being to keep the state contained in a specified compact region. The first theorem of this paper is presented and proven here. This states that the infimum data rate for which the objective is possible is precisely equal to the TFE of the plant on the region. In other words, stability as defined is possible if and only if information can be transported as fast as it is generated by the plant.

In the fourth section, the plant is placed in a metric space and the concept of local TFE (LTFE) at a point is defined, by taking appropriate limits in the TFE. Our second main result states that, under certain stabilizability conditions, local uniform asymptotic stabilizability to a fixed point is possible if and only if the data rate exceeds the plant LTFE at that point.

We then focus on deriving a formula for the LTFE of continuously differentiable plants in Euclidean space, in the fifth section. By using real Jordan forms and volume partitioning arguments, we demonstrate that the LTFE of the plant is the sum of the base-2 logarithms of the unstable eigenvalues of the Jacobian at the fixed point. This agrees exactly with results derived previously for noiseless linear plants. We then discuss extensions and open questions in the concluding section.

Throughout this paper, the real numbers are denoted by \(\mathbb{R}\), complex numbers \(\mathbb{C}\), positive integers \(\mathbb{N}\), and non-negative integers \(\mathbb{Z}_+\).

2 Topological Feedback Entropy

Before discussing the problem of data-rate-limited control, we consider how to quantify the rate at which a dynamical system with inputs generates information. The answer to this question is obviously related to the data-rate problem. However, in this section we define this information rate in an abstract manner that makes no reference to coders, controllers or feedback communication constraints. This underlines its fundamental nature as an intrinsic property of the dynamical system.

As mentioned in the introduction, Shannon’s pioneering work motivated Kolmogorov, and subsequently others, to construct definitions of entropy for completely deterministic nonlinear maps [10]. One of the most general of such constructs is the topological entropy of Adler et. al., which applies to continuous maps on compact topological spaces; see [1, 28] for details. Briefly, the idea behind this definition is to first fix an open cover \(\alpha\) for the space, ‘through’ which each iteration of the map is observed, i.e. all that is known is the sets of the open cover in which the iterations fall. Each observed open set is then inverted to yield an open set in the ‘initial state’ space. As the number of iterations increases, the family of all possible intersections of initial state open sets forms an increasingly fine open cover for the space. The topological entropy of the map is then obtained by supremizing the asymptotic rate of increase of the cardinality of this open cover over all observation open covers. This in some sense measures the fastest rate at which uncertainty about the initial state can be reduced, or equivalently the fastest rate at which initial state information can be generated.
A later definition of topological entropy by Bowen and Dinaburg [4, 28, 23] partially extended this to non-compact metric spaces, under the assumption of uniform continuity. However, the purely topological nature of Adler’s version is highly attractive, and we will use similar open cover techniques here to construct a definition of topological feedback entropy (TFE). This may appear to be an extension of normal topological entropy to maps on non-compact spaces with inputs, but there is a significant difference in interpretation, as discussed later. Note that the fact that we seek to return the state to a specified compact set via appropriate controls is also the reason that we can use open cover arguments in the style of Adler, even though Bowen’s techniques for non-compact metric spaces may appear more directly relevant. We also mention that there is also a body of recent work which explores connections between the entropy of a dynamical system and Bode’s sensitivity integral [30, 27, 11].

We first introduce some basic notation and terminology. Let $X$ be a space endowed with some topology $T$. A (possibly uncountable) collection $\alpha$ of open sets is called an open cover of a compact set $K \subseteq X$ if $K \subseteq \bigcup_{A \in \alpha} A$. By the topological definition of compactness there then exists a finite subcover of $\alpha$, i.e a finite family $\{A_p : 1 \leq p \leq r\} \subseteq \alpha$ which also covers $K$, and let $N(\alpha|K)$ denote the minimum cardinality of such finite subcovers.

Now, consider the fully observed, time-invariant, dynamical system

$$ x_{k+1} = F(x_k, u_k) \equiv F_{u_k}(x_k), \quad \forall k \in \mathbb{Z}_+, $$

where the state $x_k \in X$, the input $u_k \in U$ and $F(\cdot, u) \equiv F_u$ is continuous $\forall u \in U$. We analyze this system on a compact set $K$ with non-empty interior, under two alternative conditions of increasing strength:

**Weak Invariability [WI]**. $K$ can be made weakly invariant under $F$, i.e. there exists $t \in \mathbb{N}$ and a compact $K' \subseteq \text{int}K$ s.t. $\forall x_0 \in K \exists$ an input sequence $\{H_k(x_0)\}_{k=0}^{t-1}$ in $U$ which ensures $x_t \in \text{int}K'$.

**Strong Invariability [SI]**. $K$ can be made strongly invariant under $F$, i.e. there exists a compact $K' \subseteq \text{int}K$ s.t. $\forall x_0 \in K \exists$ an input $H_0(x_0) \in U$ which ensures $x_1 \in \text{int}K'$.

We remark that for the purposes of this section and the subsequent one, it would be possible to weaken these definitions to only require that the subsequent state $x_t$ or $x_1$ lies in the interior of $K$, without positing the existence of an inner set $K'$. However, the more stringent definition of strong invariability above, in particular, is needed in the proofs of section 4, and for the sake of a uniform approach an analogous definition has been adopted for weak invariability.

Let $\alpha$ be an open cover of $K$, $\tau$ a positive integer, and $G = \{G_k : \alpha \rightarrow U\}_{k=0}^{\tau-1}$ a sequence of $\tau$ maps that assign input variables to all sets in $\alpha$. Depending on which of the invariability conditions above holds, impose the following corresponding constraint on $\alpha$, $\tau$, and $G$:

[WI']. $\exists$ compact set $K' \subseteq \text{int}K$ s.t. $\forall x_0 \in A \in \alpha$, the sequence of inputs $G(A)$ yields $x_\tau \in \text{int}K'$, i.e.

$$ F_{G_{\tau-1}(A)} \cdots F_{G_0(A)}(A) \subseteq \text{int}K', \quad \forall A \in \alpha. $$

(2)
$[\text{SI}']$.  \(\exists\) compact set \(K' \subseteq \text{int} K\) s.t. \(\forall x_0 \in A \in \alpha\), the sequence of inputs \(G(A)\) yields \(x_k \in \text{int} K', \forall k \in [1, \ldots, \tau]\), i.e.

\[
F_{G_{\tau - 1}(A)} \cdots F_{G_0(A)}(A) \subseteq \text{int} K', \quad \forall A \in \alpha, k \in [1, \ldots, \tau]. \tag{3}
\]

To demonstrate the feasibility of \([\text{WI}']\), set \(\tau\) equal to the invariance time \(t\) in assumption \([\text{WI}].\) By the continuity of \(F_u\) and the openness of \(\text{int} K'\), \(\forall y \in K\) there is an open set \(S(y) \ni y\) s.t. \(F_{H_{\tau - 1}(y)} \cdots F_{H_0(y)}(x) \in \text{int} K', \forall x \in S(y).\) The open cover \(\alpha\) is then chosen to be a finite subcover \(\{L^1, \ldots, L^r\}\) of the open cover \(\{S(y) | y \in K\}\), guaranteed to exist by the compactness of \(K\). Let \(y^q\) be a point in \(K\) such that \(L^q = S(y^q)\) and set

\[
G_k(L^q) = H_k(y^q), \quad \forall q \in [1, \ldots, r], k \in [0, \ldots, \tau - 1]. \tag{4}
\]

By the preceding observations, we then automatically have that if \(x \in L^q \in \alpha\), then \(F_{G_{\tau - 1}(L^q)} \cdots F_{G_0(L^q)}(x) = F_{H_{\tau - 1}(y^q)} \cdots F_{H_0(y^q)}(x) \in \text{int} K'.\) This confirms the feasibility of constraint \([\text{WI}']\) under assumption \([\text{WI}].\) A similar argument demonstrates the feasibility of \([\text{SI}']\) under \([\text{SI}].\) where the functions \(H_1, \ldots, H_{\tau - 1}\) are defined recursively in terms of \(F\) and \(H_0\) by

\[
H_k(x_0) \overset{\Delta}{=} H_0(x_k), \quad x_k = F_{H_0(x_{k-1})}(x_{k-1}), \quad \forall x_0 \in K, k \in [1, \ldots, \tau - 1],
\]

and \(\tau\) can be any positive integer.

Next, let \(A_0, A_1, \ldots\) be elements of \(\alpha\) and define

\[
B_j \overset{\Delta}{=} \left\{ x_0 \in X : x_{i\tau} \in A_i, \{u_{l\tau} = G(A_{l - 1})\}, \forall i \in [0, \ldots, j]\right\}, \quad \forall j \in \mathbb{Z}_+.
\tag{5}
\]

In words, the set \(B_j\) corresponds to the region in which \(x_0\) is known to lie, given the observations \(x_{i\tau} \in A_i, 0 \leq i \leq j\), and inputs \(G(A_i) \in U^\tau, 0 \leq i \leq j - 1.\) The openness of \(B_j\) may be explicitly confirmed by writing it as

\[
B_j = A_0 \cap \Phi^{-1}_{G(A_0)}(A_1) \cap \Phi^{-1}_{G(A_0)}(A_2) \cap \cdots \cap \Phi^{-1}_{G(A_0)}(A_j), \quad \forall j \in \mathbb{Z}_+,
\tag{6}
\]

since the composition \(\Phi_{G(A)} \overset{\Delta}{=} F_{G_{\tau - 1}(A)} \cdots F_{G_0(A)}\) is continuous.

Furthermore, every \(x_0 \in K\) must lie in a set \(B_j\) of the form (5). To see this, observe that if \(x_0 \in K\) then it must lie in some open set \(A_0 \in \alpha.\) By the constraint \([\text{WI}']\) or \([\text{SI}']\), the sequence \(G(A_0)\) of \(\tau\) inputs then forces \(x_{\tau} \in K.\) Repeating this process indefinitely, it is clear that \(\forall x_0 \in K\) there is a sequence \(A_0, A_1, \ldots\) of sets in \(\alpha\) such that \(x_{i\tau} \in A_i\) with an input sequence \(\{u_{i\tau} = G(A_{i - 1})\}, \forall i \in [0, \ldots, j - 1]\). Hence \(\forall j \in \mathbb{Z}_+\)

\[
\beta_j \overset{\Delta}{=} \{B_j : A_0, \ldots, A_j \in \alpha\}
\tag{7}
\]

is an open cover for \(K.\) As no set \(B_j\) in a minimal subcover of \(\beta_j\) is contained in a union of other sets, each carries new information. Hence as \(N(\beta_j | K)\) increases, so does the amount of information gained about the initial state. The asymptotic rate of information generation of \(F\) on \(K\) with inputs in \(U,\) relative to a given triple \((\alpha, \tau, G)\), may thus be measured by

\[
\lim_{j \to \infty} \frac{\log_2 N(\beta_j | K)}{j^\tau} = \inf_{j \in \mathbb{Z}_+} \frac{\log_2 N(\beta_j | K)}{j^\tau}.
\tag{8}
\]
To verify that the limit exists and equals the infimum, we appeal to a subadditivity theorem of Polya and Szego [24, 6]. Observe from (6) that $\forall j, k \in \mathbb{Z}_+$, $\beta_{j+k}$ consists of all sets of the form

$$B_{j+k} = \left[ A_0 \cap \Phi_{G(A_0)}^{-1}(A_1) \cap \cdots \cap \Phi_{G(A_0)}^{-1}(A_j) \right]$$

$$\cap \Phi_{G(A_0)}^{-1}(A_{j+1}) \cap \cdots \cap \Phi_{G(A_0)}^{-1}(A_{j+k}),$$

with $A_0, \ldots, A_{j+k}$ running freely over $\alpha$. Note that the term inside the square brackets runs over all sets in the open cover $\beta_j$, while the argument inside the large parentheses runs over all elements of $\beta_{k-1}$. Now, constrain $\{A_i\}_{i=0}^j$ to index sets in a minimal subcover $\beta_j'$ of $\beta_j$, and $\{A_i\}_{i=j+1}^{j+k}$ to index those in a minimal subcover $\beta_{k-1}'$ of $\beta_{k-1}$. Denote the constrained family of sets $B_{j+k}$ thus formed by $\beta_{j+k}'$. To see that $\beta_{j+k}'$ is still an open cover for $K$, observe that any $x \in K$ must lie in a set $B_j' \in \beta_j'$ indexed by some sequence $\{A_i\}_{i=0}^j$ in $\alpha$. Furthermore, $\Phi_{G(A_j)}(A_j) \cdots \Phi_{G(A_0)}(x) \in K$ and thus lies in some set $B_{k-1}'$ in the minimal subcover $\beta_{k-1}'$. Hence $x \in \Phi_{G(A_0)}^{-1}(A_0) \cdots \Phi_{G(A_j)}^{-1}(A_{j+k})$, and so $\beta_{j+k}'$ is still a cover for $K$. As there are $N(\beta_j|K)$ sets in $\beta_j'$, and to each there correspond $N(\beta_{k-1}|K)$ possible sets $\Phi_{G(A_0)}^{-1} \cdots \Phi_{G(A_j)}^{-1}(B_{k-1}')$, the number of distinct elements in $\beta_{j+k}'$ cannot exceed $N(\beta_j|K)N(\beta_{k-1}|K)$. By the definition of minimal subcovers and the monotonicity of $N(\beta_k|K)$, we must then have

$$N(\beta_{j+k}|K) \leq N(\beta_j|K)N(\beta_{k-1}|K) \leq N(\beta_j|K)N(\beta_k|K), \quad \forall j, k \in \mathbb{Z}_+.$$

Polya & Szego’s subadditivity theorem [6] then states that the limit in (8) exists and is precisely equal to the infimum.

Infimizing (8) again over $(\alpha, \tau, G)$, the weak invariance topological feedback entropy (TFE) of $F$ on $K$ with inputs in $U$ is finally defined as

$$h^{wi}(F, K, U) \triangleq \inf_{\alpha, \tau, G, j \to \infty} \lim_{j \to \infty} \frac{\log_2 N(\beta_j|K)}{j^\tau} = \inf_{\alpha, \tau, G, j} \frac{\log_2 N(\beta_j|K)}{j^\tau},$$

under constraint [WI'] on $\alpha, \tau, G$ and assumption [WI] on $F, K, U$. Analogously, the strong invariance TFE is given by

$$h^{si}(F, K, U) \triangleq \inf_{\alpha, \tau, G, j \to \infty} \lim_{j \to \infty} \frac{\log_2 N(\beta_j|K)}{j^\tau} = \inf_{\alpha, \tau, G, j} \frac{\log_2 N(\beta_j|K)}{j^\tau},$$

under constraint [SI'] on $\alpha, G$ and assumption [SI] on $F, K, U$. As the constraint [SI'] is more restrictive than [WI'], it follows that $h^{si}(F, K, U) \geq h^{wi}(F, K, U)$.

The infimum in the definitions of TFE suggests that it can be interpreted as the smallest rate at which initial state information can be generated while maintaining invariance. In contrast, the standard definition(s) of topological entropy measure the largest rate at which a fixed map can generate initial state information. This distinction is apparent for the simple example of the tent map on the unit interval with an additive control term:

$$F(x, u) = 2 \min\{x, 1-x\} + u, \quad \forall x \in K = [0, 1].$$
As \( F(x, 0) \in \text{int}K \) for any \( x \in \text{int}K \), it is easy to show that the TFE for weak and strong invariance are both 0. On the other hand, the topological entropy of this map with \( u = 0 \) is strictly positive (in fact 1 bit/sample).

Observe that we trivially have the monotonicity property

\[
h_{\text{wi}}(F, K, U) \geq h_{\text{wi}}(F, K, U'), \quad \forall U' \supset U,
\]

since the inputs can have more possible values and thereby reduce the infimum in the definitions of TFE. However, a similar monotonicity property cannot be deduced for a compact \( J \subset K \) satisfying condition [WI] ([SI]) with the same input set \( U \). Even though an open cover \( \alpha \) for \( K \) is automatically an open cover for \( J \), it may not satisfy the constraint [WI'] ([SI']) on the infimization with the same \( G \) and \( \tau \). Thus we cannot conclude that TFE increases as the state region shrinks.

The feedback entropies introduced above are defined purely in terms of open sets for a very general class of maps with inputs. As we have made no reference whatsoever to coding and control structures, feedback communication constraints, or other external constructs, topological feedback entropy as defined above is an inherent property of the dynamical system (1) alone. In the next section, we close the feedback loop and discuss the significance of TFE in the particular context of data-rate-limited control. This leads to an alternative and perhaps more practically relevant characterization of TFE.

3 Invariance under Data-Rate-Limited Feedback

In this section, we investigate a class of nonlinear control problems that involve limited data rates in the feedback loop. As discussed in the introduction, such a communication constraint has a negative effect on the attainable control performance. Different approaches to analyzing and mitigating this effect have recently been described in [18, 8]. Our specific interest here is characterizing the smallest possible data rate that permits a specified compact set to be made invariant, by a causal coding and control law belonging to a general class. We then show that, in this context, the infimum data rate is precisely equal to the intrinsic information rate of the plant, as measured by its topological feedback entropy (TFE).

Let the plant be given by (1). Suppose that a sensor measures its states and is connected to a controller by a noiseless digital channel which carries one discrete-valued symbol \( s_k \) per sampling interval, selected from a coding alphabet \( S_k \) of time-varying size \( \mu_k \). The transmission data rate \( R \) of the channel may then be defined as the asymptotic average bit rate

\[
R \triangleq \lim_{k \to \infty} \frac{1}{k} \sum_{j=0}^{k-1} \log_2 \mu_j.
\]

For technical reasons, we impose the mild requirement that \( \log_2 \mu_k/k \to 0 \) as \( k \to \infty \). Suppose that each symbol transmitted by the coder may depend on all past and present states and past symbols, i.e.

\[
s_k = \gamma_k \left( \{x_i\}_{i=0}^k, \{s_i\}_{i=0}^{k-1} \right) \in S_k, \quad \forall k \in \mathbb{Z}_+,
\]
where $\gamma_k : X^{k+1} \times S_0 \times \cdots \times S_{k-1} \to S_k$ is the coder mapping at time $k$. In practice a finite-dimensional coder would obviously be desired, but the more general formulation above allows us to focus on the limitations imposed by the digital link. Assuming that the digital channel is errorless, at time $k$ the controller has $s_0, \ldots, s_k$ available and generates

$$u_k = \delta_k (\{ s_i \}_{i=0}^k) \in U, \quad \forall k \in \mathbb{Z}_+ ,$$

where $\delta_k : S_0 \times \cdots \times S_k \to U$ is the controller function at time $k$.

Define the **coder-controller** as the triple of alphabet, coder and controller sequences $(S, \gamma, \delta) \triangleq (\{ S_k \}_{k \in \mathbb{Z}_+}, \{ \gamma_k \}_{k \in \mathbb{Z}_+}, \{ \delta_k \}_{k \in \mathbb{Z}_+})$. If for some $r \in \mathbb{N}$ the coder-controller satisfies

$$S_k = S_{k \mod r}, \quad \gamma_k (\{ x_i^k \}_{i=0}^k, \{ s_i^k \}_{i=0}^{k-1}) = \gamma_{k \mod r} (\{ x_i^k \}_{i=r|k/r}^k, \{ s_i^{k-1} \}_{i=r|k/r}^{k-1}) , \quad \delta_k (\tilde{s}_k) = \delta_{k \mod r} (\{ s_i^k \}_{i=r|k/r}^k), \quad \forall k \in \mathbb{Z}_+ ,$$

we call it **periodic** with period $r$. Coding and control equations of this class are easier to implement, due to the finite memory requirement, and are also useful analytically elsewhere in this paper.

Given an asymptotic average data rate $R \geq 0$, our objective is to investigate whether there exists a coder-controller, with inputs in $U$, which renders $K$ either

**Weakly Invariant** : $\exists \tau \in \mathbb{N}$ and compact $K' \subseteq \text{int}K$ s.t. $x_{j\tau} \in \text{int}K'$, $\forall x_0 \in K$, $j \in \mathbb{N}$; or

**Strongly Invariant** : $\exists$ compact $K' \subseteq \text{int}K$ s.t. $x_k \in \text{int}K'$, $\forall x_0 \in K$, $k \in \mathbb{N}$.

We now state the first major result of this paper:

**Theorem 1** Consider the continuous-w.r.t.-state plant $F$ (1), with states in a topological space $X$, inputs lying in a set $U$ and initial state in some compact region $K$ with non-empty interior. Assume that the weak (strong) invariability assumption [WI] (resp. [SI]) holds on $F, K, U$.

For $K$ to be made weakly (strongly) invariant by a coder-controller of the form (13)-(14), the feedback data rate $R$ (12) cannot be less than the weak (strong) invariance topological feedback entropy (9) ((10)) of the plant on $K$ with input set $U$,

$$R \geq h^{\text{wi(si)}}(F, K, U).$$

Furthermore, this lower bound is tight, i.e. there exist coder-controllers that achieve weak (strong) invariance at data rates arbitrarily close to it.

This theorem relates the practical problem of data-rate-limited feedback to the abstract concept of topological feedback entropy. Recalling that the TFE of a plant measures the rate at which it generates feedback information, the result above states that invariance is possible if and only if information can be transported across the channel as fast as it is generated. This is similar to the role that Shannon’s source coding theorem plays in information theory and digital communications [25].
In light of the theorem above, it is tempting to simply define feedback entropy as the smallest data rate which permits invariance. However, the problem with such an operational definition is that it is tied to the specific assumptions imposed on the digital channel, the coder, and the controller. In contrast, TFE is completely independent of all external constructs and is thus a purer measure of the intrinsic information rate of the plant. Again, there is an analogy with source coding, where the entropy of a statistical source is defined axiomatically in terms of a functional on its distribution, instead of the smallest data rate for “reliable” communications. As mentioned in the introduction, this avoids the problems associated with different formulations of coding and “reliability”.

In the remainder of this section we present a proof of this theorem. For conciseness only weak invariance is considered; the proof for strong invariance is nearly identical. To reduce clutter, the wi superscripts and (F, K, U) arguments are dropped.

3.1 Necessity of Lower Bound

We prove the lower bound (16) by basically showing that any coder-controller which achieves weak invariance with rate \( R \) induces an open cover \( \alpha \), mapping sequence \( G \), and recurrence time \( \tau \), as defined in the previous section, with entropy rate also \( \approx R \).

For any such coder-controller \((S, \gamma, \delta)\), there exist \( \tau_0 \in \mathbb{N} \) and compact \( K' \subset \text{int}K \) s.t. \( \forall x_0 \in K \) and \( j \in \mathbb{N} \), \( x_{j\tau_0} \in \text{int}K' \). It then follows from (12) that \( \forall \varepsilon > 0 \), there exist infinitely many \( k' \in \mathbb{N} \) s.t.

\[
\frac{1}{k'} \sum_{k=0}^{k'-1} \log_2 \mu_k < R + \varepsilon/2.
\]

Set \( l = \lfloor k'/\tau_0 \rfloor \), so that \( k' = l\tau_0 - q \) for some \( q \in [0, \ldots, \tau_0 - 1] \). Then

\[
\frac{1}{l\tau_0} \sum_{k=0}^{l\tau_0-1} \log_2 \mu_k = \frac{1}{k' + q} \sum_{k=0}^{k'-1+q} \log_2 \mu_k = \frac{1}{k' + q} \sum_{k=0}^{k'-1} \log_2 \mu_k + \frac{1}{k' + q} \sum_{k=k'}^{k'-1+q} \log_2 \mu_k,
\]

\[
\leq \frac{1}{k'} \sum_{k=0}^{k'-1} \log_2 \mu_k + \frac{1}{k' + q} \sum_{k=k'}^{k'-1+q} \log_2 \mu_k,
\]

\[
< R + \varepsilon/2 + \frac{\tau_0 - 1}{k' + \tau_0 - 1} \max_{i \in [0, \ldots, \tau_0 - 1]} \log_2 \mu_{k'+i} < R + \varepsilon
\]

(17)

for \( k' \) sufficiently large, since \( \log_2 \mu_k/k \to 0 \). Let \( r = l\tau_0 \). Evidently, \( x_r \in \text{int}K' \subset K \), so if we “reset the clock” to zero and perform the coding and control again with initial state \( = x_r \) we then get a new state \( \in \text{int}K' \) at time \( 2r \). This resetting process can be repeated, so by induction we can thus convert the original, possibly recursive, coder-controller \((S, \gamma, \delta)\) into a periodic coder-controller \((S^p, \gamma^p, \delta^p)\) with period \( r \). The most important point about this conversion is that the new coder-controller achieves \( \tau_0 \)-invariance with average data rate within \( \varepsilon \) of the original (NB: period \( \neq \) invariance time). The alphabet and coding and control
equations of the periodic scheme are formally given by

\[ S^p_k = S_{k \mod r}, \]
\[ s_k = \gamma^p_k \left( \{x_i\}_{i=0}^k, \{s_i\}_{i=0}^{k-1} \right) = \gamma_{k \mod r} \left( \{x_i\}_{i=r[k/r]}, \{s_i\}_{i=r[k/r]}^{k-1} \right), \]
\[ u_k = \delta^p_k \left( \{s_i\}_{i=0}^k \right) = \delta_{k \mod r} \left( \{s_i\}_{i=r[k/r]}^k \right), \quad \forall k \in \mathbb{Z}_+. \]

Observe that with the coder-controller fixed as above, the symbol sequence \( \{s_k\}_{k=j}^{(j+1)r-1} \) is completely determined by \( x_{jr}, \forall j \in \mathbb{Z}_+ \), by a fixed map that incorporates both coder and controller functions. We can thus write

\[ \{s_k\}_{k=j}^{(j+1)r-1} = \Gamma(x_{jr}), \quad \{u_k\}_{k=j}^{(j+1)r-1} = \Delta \left( \{s_k\}_{k=j}^{(j+1)r-1} \right), \quad \forall j \in \mathbb{Z}_+, \tag{18} \]

where \( \Gamma, \Delta \) are mappings that do not change with \( j \). Now, consider the disjoint regions \( \Gamma^{-1} \left( \{c_k\}_{k=0}^{r-1} \right) \subseteq K \) as the symbol sequence \( \{c_k\}_{k=0}^{r-1} \) varies over all possible sequences in \( S_0 \times \cdots \times S_{r-1} \). The total number of distinct symbol sequences is just \( \prod_{k=0}^{r-1} \mu_k \), so the total number \( n \) of non-empty and distinct regions must be less than or equal to this. Denote these coding regions by \( C^1, \ldots, C^n \), noting that \( K \subseteq \bigcup_{i=1}^n C^i \). We can then rewrite the control equation in (18) as

\[ \{u_k\}_{k=j}^{(j+1)r-1} = \Delta^*(C^i) \text{ if } x_{jr} \in C^i, \tag{19} \]

by defining the map \( \Delta^*(C^i) = \Delta \left( \{c_k\}_{k=0}^{r-1} \right) \text{ iff } C^i = \Gamma^{-1} \left( \{c_k\}_{k=0}^{r-1} \right) \).

We are now in a position to construct the \( \tau \in \mathbb{N} \), the open cover \( \alpha \) and the mapping sequence \( G = \{G_k : \alpha \to U\}_{k=0}^{r-1} \) required in the definition of TFE. Set \( \tau = r \) and then construct the open cover \( \alpha \) as follows. Observe that \( \forall x_0 \in \text{ any coding region } C^i \),

\[ \Phi_{\Delta^*(C^i)}(x_0) \in \text{int} K', \quad \forall x_0 \in C^i, \]

where the LHS denotes the dynamical map \( F_u \) applied \( \tau = r \) times with the input sequence (19). By the continuity of \( F_u \) (hence of \( \Phi_{\Delta^*(C^i)} \)) and the openness of \( \text{int} K' \), it then follows that \( \forall x_0 \in C^i \), there is an open set \( S(x_0) \supseteq x_0 \text{ s.t. } \Phi_{\Delta^*(C^i)}(y) \in \text{int} K', \forall y \in S(x_0) \). In this way we can construct an open set \( L^i = \bigcup_{x_0 \in C^i} S(x_0) \) s.t.

\[ \Phi_{\Delta^*(C^i)}(y) \in \text{int} K', \quad \forall y \in L^i \iff \Phi_{\Delta^*(C^i)}(L^i) \subseteq \text{int} K', \quad i = 1, \ldots, n. \tag{20} \]

As \( C^i \subseteq L^i \) and \( K \subseteq \bigcup_{i=1}^n C^i \), \( \alpha = \{L^i : i = 1, \ldots, n\} \) is an open cover for \( K \). Finally, construct the mapping sequence \( G \) as

\[ G_k(L^i) = \Delta^*(C^i), \quad \forall L^i \in \alpha, \quad k = 0, \ldots, \tau - 1. \]

Substituting this construction into (20), it is then evident that the constraint \((\text{WT}')\) on \( \tau, \alpha, G \) is satisfied.

We now generate the \((\text{finite})\) open covers \( \beta_j \) of (7). Observe that the minimum cardinality \( N(\beta_j|K) \) of a subcover of \( \beta_j \) is the number of sets in \( \beta_j \), which by (7) must be \( \leq \) the number
of possible sequences \( \{A_j\}_{j=0}^j \) of sets in \( \alpha \), i.e.

\[
N(\beta_j | K) \leq n^{j+1} \Rightarrow \lim_{j \to \infty} \frac{\log_2 N(\beta_j | K)}{j} \leq \log_2 n,
\]

\[
\Rightarrow h \triangleq \inf_{\tau,\alpha,G} \lim_{j \to \infty} \frac{\log_2 N(\beta_j | K)}{j} \leq \log_2 \left( \prod_{k=0}^{\tau-1} \mu_k \right).
\]

From (17), we can ensure that \( \forall \varepsilon > 0 \), the last term on the RHS \( < R + \varepsilon \) by choosing \( \tau \equiv l_{\tau_0} \) sufficiently large. Hence \( R \geq h \). \( \Box \)

### 3.2 Achievability of the Lower Bound

To prove that data rates arbitrarily close to \( h \) can be achieved, we first show that any triple \( (\tau, \alpha, G) \) which satisfies constraint (WI') in the previous section induces a periodic coder-controller which renders \( K \tau \)-invariant. The (uninfimized) entropy with respect to such a triple is defined as

\[
H \triangleq \lim_{j \to \infty} \frac{\log_2 N(\beta_j | K)}{j},
\]

where \( \beta_j \) is defined by (6) and (7). It then follows that \( \forall \varepsilon > 0, \exists j \in \mathbb{N} \) s.t.

\[
\log_2 N(\beta_j | K) \leq \frac{H}{j} \leq \frac{H}{\varepsilon/2}.
\]

Recalling that \( \beta_j \) is an open cover for the compact set \( K \), select a minimal subcover of \( \beta_j \) and denote it by \( \{D^1, \ldots, D^m\} \), where \( m = N(\beta_j | K) \) by definition. We construct a periodic coding law using these overlapping sets via the rule

\[
s_k = \begin{cases} 
\min \{i \in [1, \ldots, m] : x_k \in D^i\} & \text{when } k \in [0, j\tau, 2j\tau, \ldots] \\
1 & \text{otherwise}
\end{cases}.
\]

Evidently, the coding alphabet size \( \mu_k = m \) when \( k \) is a multiple of \( j\tau \) and = 1 otherwise, so the (average) data rate of this coder is simply

\[
R = \frac{\log_2 m}{j\tau} = \frac{\log_2 N(\beta_j | K)}{j\tau} \leq \frac{H}{\varepsilon/2}.
\]

The next step is to construct the controller from the mapping sequence \( G \). By definition, for each set \( B_j \in \beta_j \) there are sets \( A_0, \ldots, A_j \in \alpha \) s.t. (5) holds. Upon receiving the symbol \( s_{lj\tau} = i \) which indexes an open set \( D^i \) containing \( x_{lj\tau} \in K' \) in the minimal subcover of \( \beta_j \), the controller finds \( \{A_i\}_{i=0}^j \) in \( \alpha \) which yields \( B_j = D^i \) and then applies control inputs via the periodic rule

\[
\{u_k\}_{k=(lj+q)\tau}^{(lj+q+1)\tau-1} = G(A_q), \quad \forall l \in \mathbb{Z}_+, q \in [0, \ldots, j-1].
\]

By the constraint (2), \( x_{(lj+q)\tau} \in \text{int}K' \), so that \( \tau \)-invariance is achieved at rate \( R \leq H + \varepsilon/2 \). As \( h \) is the infimum of \( H \), \( \forall \varepsilon > 0 \) we can find \( (\tau, \alpha, G) \) s.t. \( H < h + \varepsilon/2 \). Hence \( R < h + \varepsilon \) and the result follows by choosing \( \varepsilon \) arbitrarily small. \( \Box \)
The key point about the coder-controller construction in the second half of the proof is that the coder and controller do not simply index all elements of $\alpha$ and indicate which element of $\alpha$ each state lies in. This demands a data rate equal to $\tau^{-1}\log_2 N(\alpha|K)$ and ignores the fact that not all sequences $(A_0, \ldots, A_j)$ occur. A more efficient approach is to generate the initial state cover $\beta_j$ and transmit the index of an element of $\beta_j$ which contains $x_{lj\tau}, l \in \mathbb{Z}_+$. For each $l$-th “cycle” of duration $j\tau$, this suffices to determine sets $A_q$ containing $x_{(lj+q)\tau}, q = 0, \ldots, j-1$, which can then be used to generate control inputs via the mapping $G$.

Observe as well that the periodic coder-controller constructed above actually achieves a slightly stronger objective than weak invariance, since every point in the open set $L \supseteq \bigcup D^i \supseteq K$ is mapped in $\tau$ instants into the interior of $K'$. The strong invariance version of this property will be particularly useful when we discuss asymptotic stability in the next section. For convenience we state it here, without further proof:

Lemma 1 Consider the continuous-w.r.t.-state plant (1) with states in a topological space $X$, and let the compact region $K \subseteq X$ with non-empty interior satisfy the strong invariability assumption [SI] with input set $U$.

Then for any $\varepsilon > 0$, there exists a periodic coder-controller with data rate

$$R \leq h^s(F, K, U) + \varepsilon,$$

for which $\exists$ compact $K' \subseteq \text{int}K$ and open $L \supseteq K$ such that $x_k \in \text{int}K'$, $\forall x_0 \in L, k \in \mathbb{N}$.

Explicit formulae for the TFE of various plants are somewhat difficult to derive. However, for a controllable linear time-invariant plant $(A, B)$, theorem 1 and techniques adapted from [26, 21] can be used to show that the TFE for both weak and strong invariability on a set $K$ with unconstrained inputs is just $\sum_{\eta \in \sigma(A), |\eta| \geq 1} \log_2 |\eta|$, as expected.

4 Local Topological Feedback Entropy and Asymptotic Stabilizability

In many control systems, the objective is not just to keep the state of the plant (1) within some compact region $K$ but to steer it asymptotically to a specified point $x_*$, using feedback inputs approaching a constant value $u_*$. In this section we construct a local topological feedback entropy (LTFE) to characterize such situations. We then show that the smallest data rate for local uniform asymptotic stabilizability (LUAS) is precisely equal to the LTFE of the plant at the target point.

It is still assumed that $F(\cdot, u)$ is continuous $\forall u \in V$. As local uniform asymptotic stability is a stronger objective than making a compact initial state set invariant, additional assumptions will also be placed on the plant (1), as listed below:

[A ] The state space $X$ has metric $d_X$ and the inputs $u_k$ belong to a space $V$ with metric $d_V$. 

12
There is a constant input $u_\ast \in V$ and point $x_\ast \in X$ s.t. $x_\ast = F(x_\ast, u_\ast)$.

Local Strong Invariability] For any $\varepsilon > 0$, $\exists \varrho > 0$ s.t. $\forall \varepsilon' \in (0, \varrho]$ the state region $K = B_X(\varepsilon') \triangleq \{x \in X : d_X(x, x_\ast) \leq \varepsilon'\}$ satisfies the strong invariance condition [SI] with an input set $U = B_V(\varepsilon) \triangleq \{u \in V : d_V(u, u_\ast) \leq \varepsilon\}$.

With these assumptions in place, define the local topological feedback entropy (LTFE) of the plant at the target point $(x_\ast, u_\ast)$ as

$$h_\ast(F, x_\ast, u_\ast) \triangleq \lim_{\varepsilon \to 0} \limsup_{\varepsilon' \to 0} h_\text{si}(F, B_X(\varepsilon'), B_V(\varepsilon)), \quad (25)$$

under the topology of $X$ induced by its metric, where $h_\text{si}$ is the strong invariance TFE defined in (10). Note that since TFE increases with decreasing input sets (11), the outer limit is just a supremum over $\varepsilon > 0$ and hence exists in the extended half-line $[0, \infty]$.

We call the plant locally uniformly asymptotically stabilizable (LUAS) at the target point if $\forall \varepsilon > 0$, $\exists \varrho > 0$ such that $\forall \varepsilon' \in (0, \varrho]$ there is a coder-controller $(S, \gamma, \delta)$ yielding

$$\sup_{k \in \mathbb{N}, x_0 \in B_X(\varepsilon')} d_X(x_k, x_\ast) < \varepsilon', \quad \sup_{k \in \mathbb{Z}_+, x_0 \in B_X(\varepsilon')} d_V(u_k, u_\ast) \leq \varepsilon,$$

$$\lim_{k \to \infty} \sup_{x_0 \in B_X(\varepsilon')} d_X(x_k, x_\ast) = \lim_{k \to \infty} \sup_{x_0 \in B_X(\varepsilon')} d_V(u_k, u_\ast) = 0. \quad (26)$$

We now state the second main result of this paper:

**Theorem 2** Consider the continuous-w.r.t.-state plant (1) under assumptions [A]-[C] above. Any coder-controller (13)-(14) which locally uniformly asymptotically stabilizes it in the sense (26) must have a data rate $R$ (12) not less than the local topological feedback entropy (25) of the plant at the target point $(x_\ast, u_\ast)$,

$$R \geq h_\ast(F, x_\ast, u_\ast). \quad (27)$$

Furthermore, this lower bound is tight, i.e. there exist coder-controllers at data rates arbitrarily close to it that achieve (26).

Like Theorem 1, this result states that local asymptotic stabilizability is possible if and only if the rate at which information can circulate in the feedback loop is greater than the rate at which the plant generates initial state information at the target point. We present the proof of necessity and then sufficiency below.

### 4.1 Necessity

Suppose that the plant is locally stabilizable in the sense (26) at data rate $R$. For any arbitrary $\varepsilon > 0$ we can then find $\varrho > 0$ such that for any $\varepsilon' \leq \varrho$ there is an $\varepsilon_0 < \varepsilon'$ and a coder-controller yielding

$$x_{k+1} \in B_X(\varepsilon_0) \subset \text{int}B_X(\varepsilon'), u_k \in B_V(\varepsilon), \forall x_0 \in B_X(\varepsilon), \quad k \in \mathbb{Z}_+.$$
In other words, the coder-controller makes \( K = B_X(\varepsilon') \) strongly invariant with controls in \( B_V(\varepsilon) \). By Theorem 1, the data rate cannot be less than the strong invariance TFE of the plant with \( K = B_X(\varepsilon') \) and \( U = B_V(\varepsilon) \),

\[
R \geq h^{si}(F, B_X(\varepsilon'), B_V(\varepsilon)).
\]  

By definition of LTFE (25), \( \forall \vartheta > 0 \) we can find arbitrarily small \( \varepsilon \) such that

\[
\limsup_{\varepsilon' \to 0} h^{si}(F, B_X(\varepsilon'), B_V(\varepsilon)) \geq h_s(F, x_*, u_*) - \vartheta,
\]

so there must exist arbitrarily small \( \varepsilon' \) such that

\[
h^{si}(F, B_X(\varepsilon'), B_V(\varepsilon)) \geq h_s(F, x_*, u_*) - \vartheta.
\]

Substituting this into (28),

\[
R \geq h_s(F, x_*, u_*) - \vartheta.
\]

As \( \vartheta \) can be made arbitrarily small, it follows that \( R \geq h_s(F, x_*, u_*) \). \( \square \)

### 4.2 Sufficiency

We now prove that the data rate lower bound (27) is tight. By definition (25) of LTFE and the monotonicity of \( h^{si} \) with respect to input sets (11),

\[
\limsup_{\varepsilon' \to 0} h^{si}(F, B_X(\varepsilon'), B_V(\varepsilon)) \leq h_s(F, x_*, u_*) , \quad \forall \varepsilon > 0.
\]

As such, \( \forall \vartheta, \varepsilon > 0 \exists \varrho_0 > 0 \) such that

\[
h^{si}(F, B_X(\varepsilon'), B_V(\varepsilon)) \leq h_s(F, x_*, u_*) + \varrho / 2, \quad \forall \varepsilon' \in (0, \varrho_0].
\]  

Setting \( \varrho_1 = \) the minimum of \( \varrho_0 \) and the \( \varrho \) of the local strong invariability condition [C], Lemma 1 then states that for each \( \varepsilon' \in (0, \varrho_1] \) there exists an open set \( L \supset B_X(\varepsilon') \), a compact set \( K' \subset \text{int}B_X(\varepsilon') \), and a periodic coder-controller such that any initial state in \( L \) is driven into \( K' \) at every subsequent instant. Furthermore, this coder-controller can be chosen to have data rate

\[
R \leq h^{si}(F, B_X(\varepsilon'), B_V(\varepsilon)) + \varrho / 2 < h_s(F, x_*, u_*) + \theta.
\]

Now, \( \forall \varepsilon, \theta > 0, \varepsilon' \in (0, \varrho_1] \), define the set \( \mathcal{F}(\varepsilon, \varepsilon', \theta) \) of finitely switched periodic coder-controllers as follows. For each \( (S, \gamma, \delta) \in \mathcal{F}(\varepsilon, \varepsilon', \theta) \) there is a finite, strictly increasing sequence of nonnegative switching times \( \{M_i\}_{i=0}^{N-1} \) and corresponding periods \( \{T_i\}_{i=0}^{N-1} \), with \( M_{i+1} = M_i \mod T_i \), such that at any time \( k \in \{M_i, \ldots, M_{i+1} - 1\} \), the coder-controller satisfies

\[
\begin{align*}
S_k &= S_{M_i + [(k - M_i) \mod T_i]}, \\
S_k &= \gamma_{M_i + [(k - M_i) \mod T_i]} \left( \left\{ x_i \right\}_{i=M_i + T_i \lfloor (k - M_i) / T_i \rfloor + 1} \right), \\
u_k &= \delta_{M_i + [(k - M_i) \mod T_i]} \left( \left\{ s_i \right\}_{i=M_i + T_i \lfloor (k - M_i) / T_i \rfloor + 1} \right).
\end{align*}
\]

14
In other words, the coder-controller is periodic with period $T$ on each interval $[M_l, \ldots, M_{l+1} - 1]$, where for convenience $M_0 = 0, M_N = \infty$. Furthermore, let each $(S, \gamma, \delta) \in \mathcal{F}(\varepsilon, \varepsilon', \theta)$ i) have average data rate satisfying (30), and ii) render the initial state ball $B_X(\varepsilon')$ strongly invariant using control inputs $u_k \in B_V(\varepsilon)$.

Now let

$$\zeta \overset{\triangle}{=} \inf_{(S, \gamma, \delta) \in \mathcal{F}(\varepsilon, \varepsilon', \theta)} \limsup_{k \to \infty} \sup_{x_0 \in B_X(\varepsilon')} d_X(x_k, x_\ast).$$

(32)

As the periodic coder-controller corresponding to $\varepsilon'$ discussed immediately after equation (29) is clearly an element of $\mathcal{F}(\varepsilon, \varepsilon', \theta)$, we must have $\zeta < \varepsilon'$. To see that in fact $\zeta = 0$, suppose that $\zeta > 0$. By (32), $\forall \phi > 0 \exists k' \in \mathbb{N}$ and $(S', \gamma', \delta') \in \mathcal{F}(\varepsilon, \varepsilon', \theta)$ which achieves

$$\sup_{x_0 \in B_X(\varepsilon')} d_X(x_k, x_\ast) \leq \zeta + \phi, \quad \forall k \geq k'.$$

(33)

However, as discussed after (29) there is a periodic coder-controller $(S^\varepsilon, \gamma^\varepsilon, \delta^\varepsilon)$ which sends an open set $L \supset B_X(\varepsilon)$ of initial states into a closed set $K' \subseteq \mathrm{int} B_X(\varepsilon)$ at all positive times, using inputs in $B_V(\varepsilon)$ and with average data rate satisfying (30). It is straightforward to show, using openness and compactness, that there exist a) $\xi \in (\varepsilon, \varepsilon')$ such that $L \supset B_X(\varepsilon) \supset B_X(\xi)$, and b) $\zeta' \leq \zeta$ such that $K' \subseteq B_X(\zeta') \subseteq B_X(\xi)$. Thus choose $\phi \leq \xi - \zeta$ in (33), apply $(S', \gamma', \delta') \in \mathcal{F}(\varepsilon, \varepsilon', \theta)$, and then switch to the periodic coder-controller $(S^\varepsilon, \gamma^\varepsilon, \delta^\varepsilon)$ at a suitably large time $k = k'$, when $x_{k'}$ lies inside $B_X(\xi)$. We then have a new finitely switched periodic coder-controller $(S, \gamma, \delta) \in \mathcal{F}(\varepsilon, \varepsilon', \theta)$ which guarantees that for any $x_0 \in B_X(\varepsilon')$, $d_X(x_k, x_\ast) \leq \zeta' < \zeta$, $\forall k > k'$. This contradicts the definition of $\zeta$ as the infimum (32) so we conclude that $\zeta = 0$.

By (33), we have thus shown that $\forall \varepsilon > 0$ there exists $g_{1} > 0$ such that $\forall \theta, \phi > 0, \varepsilon' \in (0, g_{1}]$, there is a coder-controller $\in \mathcal{F}(\varepsilon, \varepsilon', \theta)$ which takes the initial state ball $B_X(\varepsilon')$ into $B_X(\phi)$ at all sufficiently large times $k \geq k' + 1$, with controls $u_k \in B_V(\varepsilon)$ and the state remaining in some compact ball lying strictly inside $B_X(\varepsilon')$ at all times. Furthermore, as the average data rate of each periodic “section” satisfies (30), so does the overall data rate.

It is now straightforward to construct a coder-controller which achieves local uniform asymptotic stability in the sense (26). Let $\{g_{n}\}_{n=0}^{\infty}$ be any sequence of input ball radii tending monotonically to zero and $\{\varepsilon'_{n}\}_{n=0}^{\infty}$ a sequence of corresponding initial state ball radii, as per the definition of local strong invariance in assumption [C]. As each $\varepsilon'_{n} > 0$ can be as small as pleased, let $\varepsilon'_{n}$ tend monotonically to zero as well. Set $\phi_{1} = \varepsilon'_{n+1}$ and let $k'_{1}$ be the time it takes for the corresponding coder-controller $(S^i, \gamma^i, \delta^i) \in \mathcal{F}(\varepsilon_i, \varepsilon'_i, \theta)$ to take the state ball $B_X(\varepsilon'_i)$ into $B_X(\varepsilon'_{i+1})$. Define $t_i \overset{\triangle}{=} \sum_{l=0}^{i-1} k'_{l}, \forall l \in \mathbb{N}$, with $t_0 \overset{\triangle}{=} 0$. Construct an (infinitely switched periodic) coder-controller $(S, \gamma, \delta)$ by applying $(S^i, \gamma^i, \delta^i)$ during times $k \in [t_{i-1}, t_{i} - 1]$, $\forall i \in \mathbb{Z}_+$. Then during each such interval the controls and states are respectively confined to balls $B_V(\varepsilon_i)$ and $B_X(\varepsilon'_i)$ respectively, with radii tending monotonically to zero. Furthermore, by the strong invariance property of the finitely switched periodic coder-controllers used to construct it, the state is confined to a compact set in the interior of $B_X(\varepsilon'_i) = B_X(\varepsilon')$. Finally, as each periodic section has average data rate satisfying (30), the asymptotic average data rate of $(S, \gamma, \delta)$ also satisfies (30). □
5 Local Uniform Asymptotic Stability in Euclidean Space

In this section we place the plant (1) and its inputs in Euclidean spaces, and turn our attention to deriving an explicit formula for the local topological feedback entropy (LTFE) of the plant at a fixed point. To do so, we exploit Theorem 2, which states that the LTFE is precisely equal to the infimum feedback data rate for local uniform asymptotic stabilizability (LUAS) in the sense (26). We then use local real Jordan forms and volume partitioning arguments to derive an expression for the infimum data rate, and hence the LTFE.

First, certain conventions need to be defined. Sequences \( \{a_j\}_{j=0}^{k} \) are denoted \( \tilde{a}_k \) and \( \| \cdot \| \) represents either the Euclidean norm on a vector space or the matrix norm induced by it. Matrices and vectors are written in boldface. Lebesgue measure is denoted \( \lambda \), the \( n \times n \) identity matrix is denoted by \( I_n \), the \( m \times n \) zero matrix by \( 0_{m \times n} \), the \( m \times n \) matrix \( [I_m \ 0_{m \times (n-m)}] \) by \( I_{m \times n} \), and the spectrum of a matrix is represented as \( \sigma(\cdot) \), with multiple eigenvalues permitted.

Let the state space \( X = \mathbb{R}^n \), the input space \( V = \mathbb{R}^m \), and assume that \([A]-[C]\) from the previous section still hold, with the following additional assumptions:

[D] Continuous differentiability: \( F(\cdot, \cdot) \) is differentiable once with continuous 1st order partial derivatives.

[E] The pair \((A, B)\) is controllable, where \( A \) and \( B \) are the Jacobians of \( F \) w.r.t. state and control respectively at \((x_*, u_*)\).

The main result of this section follows:

**Theorem 3** Let assumptions [A]-[E] hold on the plant \( F \) (1). Then the local topological feedback entropy (25) of the plant at the fixed point \((x_*, u_*)\) is given by

\[
h_*(F, x_*, u_*) = \sum_{\eta \in \sigma(A) : |\eta| \geq 1} \log_2 |\eta|, \tag{34}
\]

where \( A \) is the Jacobian of \( F \) with respect to state, evaluated at the set-point, and \( \sigma(A) \) is the spectrum of \( A \).

This theorem states that the rate at which a plant generates information at a fixed point is determined by the unstable local open-loop dynamics at the desired set-point. The RHS is simply the base-2 rate at which a volume in the local unstable subspace increases over time, so LTFE here measures the rate at which initial state uncertainty volumes are increased by the action of the plant dynamics. Note that for the case of a linear system, this result is consistent with the work of [26, 2, 21] on infimum data rates for stabilizability in various other senses.

The remainder of this section is devoted to proving Theorem 3. From Theorem 2, we can do so by first showing that for local uniform asymptotic stabilizability in the sense (26)
with some coder-controller (13)-(14), the data rate \( R \) (12) must satisfy
\[
R \geq \sum_{\eta \in \sigma(A) : |\eta| \geq 1} \log_2 |\eta|.
\]
(35)

This is done in the following subsection, using the volume interpretation mentioned above. We then demonstrate the tightness of the data rate lower bound in subsection 5.2, by constructing a coder-controller that achieves local uniform asymptotic stability at a data rate arbitrarily close to it.

5.1 Necessity

The intuition we use to prove the necessity of (35) is that the open-loop growth in unstable subspace uncertainty volume near the set-point must be counteracted by a reduction in volume due to the coding partitions. Similar ideas have been employed for linear plants [26, 2, 21]. However, the nonlinearity of the plant here complicates matters and necessitates rather different technical tools.

Suppose that local uniform asymptotic stability has been achieved by some coder-controller \((S, \gamma, \delta)\) with an initial state ball \(B_X(l_0)\). Recall that \(A\) is the Jacobian of the dynamical map w.r.t. the state at the set-point,\n\[
A \triangleq \frac{\partial F}{\partial x}(x^*, u^*) \in \mathbb{R}^{n \times n},
\]
(36)
and let \(T \in \mathbb{R}^{n \times n}\) be an orthonormal real similarity transform such that
\[
J \triangleq TAT^T \in \mathbb{R}^{n \times n}
\]
(37)
is a real Jordan form; see e.g. [15] for details. Briefly, \(J\) has a block-diagonal structure with each block possessing either one real or two complex conjugate eigenvalues, not counting repeats. In terms of plant dynamics, \(z_k \triangleq Tx_k\) can then be interpreted as a vector of modes with decoupled open-loop dynamics near the target point.

Define \(z^u_k \in \mathbb{R}^d\) to be the vector of those modes governed by eigenvalues of \(J\) not less than 1 in magnitude. Assuming without loss of generality that the blocks of \(J\) are ordered according to descending eigenvalue magnitudes, \(z^u_k = I_{d \times n}x_k\), with \(z^*_u = I_{d \times n}x^*_u\).

It then trivially follows that \(||x_k - x^*_u|| = ||z_k - z^*_u|| \geq ||z^u_k - z^*_u||\), so that \(z^u_k \to z^*_u\) uniformly over \(x_0 \in B_X(l_0)\).

Next, for any symbol sequence \(\tilde{c}_{k-1} \in \tilde{S}_{k-1}\) define the locally unstable uncertainty set
\[
I_k(\tilde{c}_{k-1}) \triangleq \{z^u \in \mathbb{R}^d : \exists x_0 \in B_X(l_0) \text{ s.t. } \tilde{s}_{k-1} = \tilde{c}_{k-1} \& z^u = z^u_k\},
\]
(39)
i.e. the set of all possible points that $z_k^u$ can take given the symbol sequence $\tilde{s}_{k-1} = \tilde{c}_{k-1}$.

Then define the maximum locally unstable uncertainty volume

$$v_k \triangleq \max_{\tilde{c}_{k-1}} \lambda \{ I_k(\tilde{c}_{k-2}) \},$$

Now, if $r$ denotes the supremum distance of points in a set $H \subset \mathbb{R}^d$ from $z_k^u$, then $H$ is obviously wholly contained in the ball of radius $r$ centred at $z_k^u$. Hence

$$\lambda\{H\} \leq \beta r^d = \beta \sup_{z^u \in H} \| z - z_k^u \|^d; \quad \forall H \subset \mathbb{R}^d,$$

where $\beta$ is the $d$-dimensional sphere constant. Thus

$$l_k \triangleq \sup_{x_0 \in B_X(l_0)} \{ \| z_k - z_* \|, \| u_k - u_* \| \} \geq \sup_{x_0 \in B_X(l_0)} \| z_k^u - z_*^u \|, \quad (41)$$

$$= \max_{\tilde{c}_{k-1}} \sup_{x_0 \in B_X(l_0), \tilde{s}_{k-1} = \tilde{c}_{k-1}} \| z_k^u - z_*^u \|; \quad (42)$$

$$\geq \max_{\tilde{c}_{k-1}} \beta^{-1/d} \lambda \{ z_k^u - z_*^u : x_0 \in B_X(l_0), \tilde{s}_{k-1} = \tilde{c}_{k-1} \}^{1/d},$$

$$= \beta^{-1/d} \max_{\tilde{c}_{k-1}} \lambda \{ I_k(\tilde{c}_{k-1}) \} \equiv \beta^{-1/d} v_k^{1/d}; \quad (43)$$

i.e., $v_k \to 0$ as well. The equality (42) is a consequence of the invariance of Lebesgue measure to constant translations, while the equality in (41) follows from the fact that, with the coder-controller fixed, the same $x_0$ cannot yield two different symbol sequences, i.e. the regions $\{ x_0 \in \mathbb{R}^n : x_0 \in B_X(l_0) \tilde{s}_{k-1} = \tilde{c}_{k-1} \} \tilde{c}_{k-1} \tilde{s}_{k-1}$ must be disjoint and exhaustive.

A recursive lower bound for the worst-case volume $v_k$ will now be derived. Observe that

$$v_{k+1} \triangleq \max_{\tilde{c}_{k-1}} \lambda \{ z_{k+1}^u : \tilde{s}_k = \tilde{c}_k \} = \max_{\tilde{c}_k} \lambda \{ G(z_k^u, z_k^s, u_k) : \tilde{s}_k = \tilde{c}_k \},$$

where for convenience, the locally stable components of $Tx_k$ are denoted $z_k^s \in \mathbb{R}^{n-d}$ and

$$G(z^u, z^s, u) \triangleq I_{d \times n} TF(x, u).$$

The next step is to replace the nonlinear function $G$ with its local linearization. As $F$ has continuous first order derivatives,

$$G(z^u, z^s, u) = z^u + J^u (z^u - z^u_*) + I_{d \times n} TB (u - u_*) + o(l), \quad \forall \| z - z_* \|, \| u - u_* \| \leq l,$$

where the $o(l)$ term $\to 0$ uniformly over $z,u$ and $J^u \triangleq I_{d \times n} TJT^T I_{n \times d} \in \mathbb{R}^{d \times d}$, the real Jordan form governing the locally unstable subspace. From this it can be established that $\exists \varepsilon(l) \to 0$ s.t. for any $H \subset \{ (z, u) \in \mathbb{R}^n \times \mathbb{R}^m : \| z - z_* \|, \| u - u_* \| \leq l \}$,

$$\lambda \{ G(z^u, z^s, u) : (z, u) \in H \} \geq [1 - \varepsilon(l)] \lambda \{ z^u + J^u(z^u - z^u_*) + I_{d \times n} TB u : (z, u) \in H \}. \quad (44)$$
Substituting this into (44) with \( l = l_k, \) \( z^n_k = z^n, \) \( \bar{z}^n_k = \bar{z}^n, \) \( u_k = u \) and \( \{(z_k, u_k) : \hat{s}_k = \hat{c}_k\} = H, \) and writing \( \varepsilon(l) \equiv \varepsilon_k, \)

\[
v_{k+1} \geq (1 - \varepsilon_k) \max_{\hat{c}_k} \lambda \left\{ z^n_k + J^n(u^n_k - z^n_k) + I_{d \times n} \mathcal{B} \delta (\hat{s}_k) : \hat{s}_k = \hat{c}_k \right\},
\]

\[
= (1 - \varepsilon_k) \max_{\hat{c}_k} \lambda \left\{ J^n(z^n_k - z^n_k) + I_{d \times n} \mathcal{B} \delta (\hat{c}_k) : \hat{s}_k = \hat{c}_k \right\},
\]

\[
= (1 - \varepsilon_k) \max_{\hat{c}_k} \lambda \left\{ J^n(u^n_k - z^n_k) + I_{d \times n} \mathcal{B} \delta (\hat{c}_k) : \hat{s}_k = \hat{c}_k \right\},
\]

\[
= (1 - \varepsilon_k) \max_{\hat{c}_k} |\det J^n| \lambda \left\{ z^n_k : \hat{s}_k = \hat{c}_k \right\}, \tag{45}
\]

\[
= (1 - \varepsilon_k) |\det J^n| \max_{\hat{c}_k} \left\{ \max_{c_k} \lambda \left\{ z^n_k : s_k = c_k, \hat{s}_{k-1} = \hat{c}_{k-1} \right\} \right\}, \tag{46}
\]

where (45) follows from the translation-invariance of Lebesgue measure and (46) describes the effect of an invertible linear transformation on volume.

The trivial decomposition (47) leads to an observation that is the heart of the necessity argument developed here. The uncertainty sets \( \{z^n_k : s_k = c_k, \hat{s}_{k-1} = \hat{c}_{k-1}\} \) are not necessarily disjoint as the single symbol \( c_k \) runs over its possible values. However, since \( s_k \) is a well-defined function of the initial state and previous symbols, their union must cover the set \( \{z^n_k | \hat{s}_{k-1} = \hat{c}_{k-1}\}, \) i.e.

\[
\{z^n_k : \hat{s}_{k-1} = \hat{c}_{k-1}\} = \bigcup_{c_k \in S_k} \{z^n_k : s_k = c_k, \hat{s}_{k-1} = \hat{c}_{k-1}\},
\]

\[
\Rightarrow \lambda \{z^n_k : \hat{s}_{k-1} = \hat{c}_{k-1}\} \leq \sum_{c_k \in S_k} \lambda \{z^n_k : s_k = c_k, \hat{s}_{k-1} = \hat{c}_{k-1}\},
\]

\[
\leq \mu_k \max_{c_k \in S_k} \lambda \{z^n_k : s_k = c_k, \hat{s}_{k-1} = \hat{c}_{k-1}\}. \tag{48}
\]

Substituting this into (47),

\[
v_{k+1} \geq (1 - \varepsilon_k) |\det J^n| \max_{\hat{c}_k} \mu_k^{-1} \lambda \{z^n_k : \hat{s}_{k-1} = \hat{c}_{k-1}\},
\]

\[
= \left( 1 - \varepsilon_k \right) |\det J^n| \frac{v_k}{\mu_k} \geq v_0 \prod_{j=0}^{k} \left( 1 - \varepsilon_j \right) |\det J^n| \frac{1}{\mu_j},
\]

19
by repeating the recursion \( k \) times. As \( v_0 > 0 \) and \( v_k \to 0 \), for all sufficiently large \( k \)

\[
\prod_{j=0}^{k} \mu_j \geq \prod_{j=0}^{k} (1 - \varepsilon_j) |\det J^u|,
\]

\[
\Rightarrow \frac{1}{k+1} \sum_{j=0}^{k} \log_2 \mu_j \geq \log_2 |\det J^u| + \frac{1}{k+1} \sum_{j=0}^{k} \log_2 (1 - \varepsilon_j),
\]

\[
\Rightarrow R \triangleq \liminf_{k \to \infty} \frac{1}{k+1} \sum_{j=0}^{k} \log_2 \mu_j \geq \log_2 |\det J^u| + \liminf_{k \to \infty} \frac{1}{k+1} \sum_{j=0}^{k} \log_2 (1 - \varepsilon_j),
\]

\[
= \log_2 |\det J^u| + \sum_{\eta \in \sigma(A)}:|\eta| \geq 1 \log_2 |\eta|,
\]

where (50) follows since \( \varepsilon_j \to 0 \). This completes the proof of necessity for (35).

5.2 Tightness of Bound

The final step in proving Theorem 3 is to establish that the bound (35) is achievable, i.e. there exist coding and control schemes with asymptotic average data rates arbitrarily close to it that still achieve local uniform asymptotic stability. In order to do so a specific coder-controller will be constructed and analyzed.

Note that this scheme is not proposed as a practical control law, as issues such as performance, robustness and complexity would then need to be considered. It is intended only to demonstrate that the data rate lower bound (35) can be approached arbitrarily closely from above, making it the infimum data rate for local uniform asymptotic stabilizability (LUAS).

First, recall that the real Jordan form \( J \) of the Jacobian of \( F \) w.r.t. state at the set-point has a block diagonal structure

\[
J \equiv \text{diag}(J_1, \ldots, J_r) \in \mathbb{R}^{d \times d}.
\]

Each block \( J_i \in \mathbb{R}^{d_i \times d_i} \) has either one distinct, real eigenvalue \( \eta_i \) of multiplicity \( m_i = d_i \), or two distinct, complex conjugate eigenvalues \( \eta_i, \bar{\eta}_i \) of multiplicities \( m_i = d_i/2 \). The components of the transformed state vector \( z_k \) corresponding to the block \( J_i \) are denoted \( \mathbf{z}^{(i)}_k \in \mathbb{R}^{d_i} \). A further property of these blocks that will be used later is that \( \exists \kappa > 0 \) s.t.

\[
\| J_i^T \| \leq \kappa \tau^{d_i-1}|\eta_i|^\tau, \quad \forall N \in \mathbb{N}.
\]

This states that powers of a Jordan block grow exponentially according to the magnitude of its eigenvalue, with possibly an extra polynomial factor arising from multiplicity.\(^1\)

\(^1\)To show this, observe that each real Jordan block is similar to a standard Jordan block (or two) and apply an argument from [15], pg. 138

20
Suppose that at time $k = 0$, $\|z_0 - z^*\| \leq$ some known $b_0$. Let $R_0$ be any number that satisfies (35) and divide times $k \in \mathbb{Z}_+$ into epochs $[j\tau, \ldots, (j + 1)\tau - 1]$, $j \in \mathbb{Z}_+$, of some uniform integer duration $\tau$. At time $k = j\tau$, suppose $b_j$ is a uniform bound such that

$$\|z_{j\tau} - z^*\| \leq b_j, \quad \forall \|z_0 - z^*\| \leq b_0.$$ 

The way in which $\{b_j\}_{j \in \mathbb{N}}$ is generated will be specified later. Overbound this region by an $n$-dimensional cube centred at $z^*$ with sides of length $2b_j$. Then partition this cube by dividing each coordinate axis corresponding to a component of $z_{j\tau}^{(i)}$ into $M_i$ intervals of equal length,

$$M_i \overset{\Delta}{=} \lceil |\xi_\eta| \rceil + 1 \quad \text{for } |\eta_i| \geq 1, \quad M_i \overset{\Delta}{=} 1 \quad \text{for } |\eta_i| < 1,$$

where $\lceil \cdot \rceil$ denotes rounding down and the parameter $\xi > 1$ is selected to satisfy

$$0 < d \log_2 \xi < R_0 - \sum_{|\eta_i| \geq 1} d_i \log_2 |\eta_i| \equiv R_0 - \sum_{|\eta| \in \sigma(A); |\eta| \geq 1} \log_2 |\eta|. \quad (53)$$

Note that as the right-hand side (RHS) is guaranteed positive, candidates for $\xi$ always exist. The total number of subcuboids thus formed is $\prod_{i=1}^r M_i^{d_i}$, so index them in a predefined way by the integers $0, \ldots, \mu_{j\tau} - 1$, where

$$\mu_{j\tau} \overset{\Delta}{=} \prod_{i=1}^r M_i^{d_i}. \quad (54)$$

At time $j\tau$, transmit the index $s_{j\tau}$ of the one which contains $z_{j\tau}$. At remaining times in the epoch $j\tau + 1 \leq k \leq (j + 1)\tau - 1$, set $\mu_k = 1$, i.e. transmit no information. Clearly, the asymptotic average data rate is

$$R = \frac{1}{\tau} \log_2 \left( \prod_{i=1}^r M_i^{d_i} \right) = \frac{1}{\tau} \sum_{|\eta_i| \geq 1} d_i \log_2 (\lceil |\xi_\eta| \rceil + 1),$$

$$\leq \frac{1}{\tau} \sum_{|\eta_i| \geq 1} d_i \log_2 (2|\xi_\eta|),$$

$$= \frac{d}{\tau} + d \log_2 \xi + \sum_{|\eta_i| \geq 1} d_i \log_2 |\eta_i| < R_0 \quad (55)$$

by (53), for sufficiently large $\tau$.

Now consider the controller at the other end of the channel, which receives the symbol $s_{j\tau}$ at time $j\tau$. As it also knows the uniform bound $b_j$ and the number of intervals $M_i$, $i = 1, \ldots, r$, it then knows which subcuboid $z_{j\tau}$ lies in and uses its centre as an estimate $q_{j\tau}$. Hence

$$\|z_{j\tau}^{(i)} - q_{j\tau}^{(i)}\| = \left( \sum_{h=1}^{d_i} |z_{j\tau}^{(i,h)} - q_{j\tau}^{(i,h)}|^2 \right)^{1/2} \leq \left[ \sum_{h=1}^{d_i} \left( \frac{b_j}{M_i} \right)^2 \right]^{1/2} = \frac{\sqrt{d_i} b_j}{M_i}.$$
where the additional superscript $h$ denotes the scalar components of vectors in $\mathbb{R}^d$. It then calculates the next $n$ control signals $u_{\tau j}, \ldots, u_{\tau j+n-1}$ by using the controllability of $(A, B)$, and hence of $(J, TB)$, to force the linearised system with nominal initial state $q_j$ to the origin in $n$ steps, i.e. by solving

$$\sum_{k=j+1}^{j+n} J^{\tau j+n-k}TB(u_k - u_*) \equiv W(y_j - y_*) = -J^nT(q_j - z_*), \quad \forall j \in \mathbb{Z}_+,$$

(57)

where $W \triangleq [TB \ldots J^{n-1}TB] \in \mathbb{R}^{n \times nm}$ and $y_j \triangleq [u'_{\tau j+n} \ldots u'_{\tau j+n-1}]' \in \mathbb{R}^{nm}$. The remaining control signals in the epoch are set to $u_*$. Note that as the controllability matrix $W$ has rank $n$, it possesses $n$ linearly independent columns $\in \mathbb{R}^n$ and only the corresponding $n$ scalar components of the stacked control vector $y_j$ are needed. If the inverse of the matrix formed by these columns is padded with $nm-n$ null rows, corresponding to the unnecessary components of $y_j$, to form $V \in \mathbb{R}^{nm \times n}$, then the stacked control may be expressed more explicitly as

$$y_j - y_* = -VJ^n(q_j - z_*),$$

(58)

i.e. a linear function of $q_j - z_*$. The crucial remaining step is to determine how to update the uniform upper bound $b_j$ from one epoch to the next. In the following a recursion for $b_j$ will be sought which decays exponentially to zero for a sufficiently large but fixed epoch duration $\tau$. As $b_j \geq \|z_{\tau j} - z_*\|$ by definition, this will effectively complete the proof.

First observe that, as $q_j \in \mathbb{R}^n$ lies in a cube of sides $2b_j$ centered at $z_*$, $\|q_j - z_*\| \leq \sqrt{n}b_j$. In addition, by (58) $\exists C \triangleq \|VJ^n\|$ independent of $\tau$ and $b_j$ s.t. $\|u_k - u_*\| \leq Cb_j$ for all times $k$ in the $j$th epoch. Now consider the map $F$ iterated $\tau$ times from some initial state $z$ and with inputs $v_0, \ldots, v_{\tau - 1}$, denoted $F_{v_{\tau - 1}}F_{v_{\tau - 2}} \cdots F_{v_0}(z)$ for convenience. By the continuous differentiability of $F$, it follows that $\forall \|z - z_*\| \leq b$, $\|v_t - u_*\| \leq Cb$, and $t \in [0, \ldots, \tau - 1]$,

$$\left\|F_{v_{\tau - 1}} \cdots F_{v_0}(z) - z_* - J'(z - z_*) - \sum_{t=0}^{\tau - 1} J_{t+1}^{\tau - 1-t}TB(v_t - u_*)\right\| \leq \zeta(b)b = o(b),$$

(59)

where $\zeta(b)$ may depend on $\tau$ but $\to 0$ as $b \to 0$. Substituting $z = z_{\tau j}, v_t = u_{\tau j+t}$, rearranging
and looking at each $i$th local mode,

$$
\|z_{j+1i} - z_ia\| \leq \left| J_i^7(z_{j+1i}^{(a)} - z_ia) + \sum_{k=j+1}^{j_1i} J_i^{(j+1)i-1} \{TB(u_k - u_a)\}\right| + \zeta(b_j)b_j,
$$

$$
\|z_{j+1i} - z_ia\| \leq \|J_i^7(z_{j+1i}^{(a)} - z_ia)\| + \zeta(b_j)b_j, \quad (57)
$$

$$
\|z_{j+1i} - z_ia\| \leq \|J_i^7(z_{j+1i}^{(a)} - z_ia)\| + \zeta(b_j)b_j, \quad (58)
$$

$$
\|z_{j+1i} - z_ia\| \leq \|J_i^7(z_{j+1i}^{(a)} - z_ia)\| + \zeta(b_j)b_j, \quad (59)
$$

$$
\|z_{j+1i} - z_ia\| \leq \|J_i^7(z_{j+1i}^{(a)} - z_ia)\| + \zeta(b_j)b_j, \quad (60)
$$

$$
\|z_{j+1i} - z_ia\| \leq \|J_i^7(z_{j+1i}^{(a)} - z_ia)\| + \zeta(b_j)b_j, \quad (61)
$$

where (60) follows from (57), (61) from (51) and (56), and (62) from the triangle inequality.

Now, consider the $b_j$-independent term $\beta(\tau)$ on the RHS of (63). If $|\eta| < 1$, $M_i = 1$ and $\tau^{d_i-1}|\eta|^\tau \to 0$ as $\tau \to \infty$. If $|\eta| \geq 1$, $M_i \geq |\xi|\eta|^\tau$ from (52), so

$$
\tau^{d_i-1}|\eta|^\tau \sqrt{d_i} \to 0 \quad \text{as} \quad \tau \to \infty.
$$

Hence, $\beta(\tau)$ can be made arbitrarily small, independently of $b_j$. Select some value for $\tau$ large enough that $\beta(\tau) < 1$. As for any fixed $\tau \zeta(b) \to 0$, set $b_0$ so that $\forall b \leq b_0$, $\beta(\tau) + \sqrt{\tau}\zeta(b) \leq$ some selected $\chi < 1$. It then follows that $b_1 \leq \chi b_0 < b_0$, and by induction it can be established that $b_{j+1} \leq \chi b_j < b_j$.

Hence $b_j \leq \chi^j b_0 \to 0$ exponentially. Recall that there is a constant $C > 0$ such that $\|u_k - u_a\| \leq Cb_j, \forall k \in [j+1, (j+1)|\tau - 1]$. The continuity of $F$ and the linear dependence of $u_k - u_a$ on $q_j - z_*$ (58) can similarly be used to show that $\exists D > 0$ such that $\|x_k - x_*\| \leq Db_j, \forall k \in [j+1, (j+1)|\tau - 1]$. Thus for all $x_0 \in B_X(b_0)$ a ball of sufficiently small radius $b_0$ centered at $x_*$, the plant has been locally exponentially stabilized in state and control using controls $u_k \in BV(Cb_0)$. □.

6 Conclusion

This paper addressed the fundamental question of how to define the intrinsic rate at which a nonlinear plant generates stability information. By using general open cover techniques, the
concept of topological feedback entropy (TFE) was introduced and proposed as a rigorous measure of the rate at which a plant on a non-compact topological space generates initial state information. The problem of data-rate-limited stabilization was then addressed. It was proven that the infimum feedback data rate to be able to keep the states confined to a compact set is precisely equal to the TFE of the plant on the target set. By taking appropriate limits in a metric space, the notion of local TFE (LTFE) was then defined at fixed points of the plant. It was then shown that local uniform asymptotic stabilizability to a fixed point is possible if and only if the data rate exceeds the plant LTFE at the fixed point. For continuously differentiable plants in Euclidean space, a formula for LTFE as the sum of the base-2 logarithms of the unstable eigenvalues of the Jacobian at the fixed point was then derived. Extensions of these results to nonlinear systems with disturbances are presently being investigated.
