**Abstract**—Methods for proving that concurrent software does not leak its secrets has remained an active topic of research for at least the past four decades. Despite an impressive array of work, the present situation remains highly unsatisfactory. With contemporary compositional proof methods one is forced to choose between *expressiveness* (the ability to reason about a wide variety of security policies), on the one hand, and *precision* (the ability to reason about complex thread interactions and program behaviours), on the other. Achieving both is essential and, we argue, requires a new style of compositional reasoning.

We present VERONICA, the first program logic for proving concurrent programs information flow secure that supports compositional, high-precision reasoning about a wide range of security policies and program behaviours (e.g. expressive declassification, value-dependent classification, secret-dependent branching). Just as importantly, VERONICA embodies a new approach for engineering such logics that can be re-used elsewhere, called *decoupled functional correctness* (DFC). DFC leads to a substantially simpler logic, even while achieving this unprecedented combination of features. We demonstrate the virtues and versatility of VERONICA by verifying a range of example programs, beyond the reach of prior methods.

## 1. Introduction

Software guards our most precious secrets. More often than not, software systems are built as a collection of concurrently executing threads of execution that cooperate to process data. In doing so, these threads collectively implement security policies in which the sensitivity of the data being processed is often data-dependent [1]–[10], and the rules about to whom it can be disclosed and under what conditions can be non-trivial [11]–[16]. The presence of concurrency greatly complicates reasoning, since a thread that behaves securely when run in isolation can be woefully insecure in the presence of interference from others [10], [17]–[19] or due to scheduling [20], [21].

For these reasons, being able to formally prove that concurrent software does not leak its secrets (to the wrong places at the wrong times) has been an active and open topic of research for at least the past four decades [22], [23]. Despite an impressive array of work over that time, the present situation remains highly unsatisfactory. With contemporary proof methods one is forced to choose between *expressiveness* (e.g. [24]–[27]), on the one hand, and *precision* (e.g. [10], [19], [28]–[32]), on the other.

By expressiveness, we mean the ability to reason about the enforcement of a wide variety of security policies and classes thereof, such as state-dependent secure declassification and data-dependent sensitivity. It is well established that, beyond simple noninterference [33] (“secret data should never be revealed in public outputs”), there is no one-size-fits-all solution to specifying information flow policies [13], and that different applications might have different interpretations on what adherence to a particular policy means.

By precision, we mean the ability to reason about complex thread interactions and program behaviours. This includes not just program behaviours like secret-dependent branching that are beyond the scope of many existing proof methods (e.g. [10], [19]). Moreover, precision is aided by reasoning about each thread under local assumptions that it makes about the behaviour of the others [29], [34]. For instance [10], suppose thread *B* receives data from thread *A*, by acquiring a lock on a shared buffer and then checking the buffer contents. Thread *B* relies on thread *A* having appropriately labelled the buffer to indicate the (data-dependent) sensitivity of the data it contains and, while thread *B* holds the lock, it relies on all other threads to avoid modifying the buffer (to preserve the correctness of the sensitivity label). Precise reasoning here should take account of these kinds of assumptions when reasoning about thread *B* and, correspondingly, should prove that they are adhered to when reasoning about thread *A*.

A key enabler to achieve both expressiveness and precision is *compositionality*. For a proof method to support expressiveness and precision, it must be designed to prove a general security definition that can be instantiated to encode a wide range of security policies. Doing so is difficult, unless in a concurrent setting the proof method is *compositional* [35]–[38], i.e. using it to prove each thread secure establishes the security of the concurrent program.

So far it has remained an open problem of how to design a proof method (e.g. a security type system [39] or program logic [40]) that is (a) compositional, (b) supports proving a general enough definition of security to encode a variety of security policies, and (c) supports precise reasoning.

In addition, even the existing proof methods that must forgo one of these desirable properties have their own shortcomings. As we explain in Section 2.1, so far even achieving compositionality with some degree of precision (forgoing expressiveness) has produced logics that are complex [19] and costly to develop [10], hindering usability, maintainability and extensibility.

We argue that achieving compositionality, expressiveness and precision together requires a new style of program logic for information flow security.

In this paper, we present VERONICA. VERONICA is, to our knowledge, the first compositional program logic for proving concurrent programs information flow secure that supports high-precision reasoning about a wide range of security policies and program behaviours (e.g. expressive declassification, value-dependent classification, secret-dependent branching). Just as importantly, VERONICA embodies a new approach for engineering such logics that can be re-used elsewhere. This approach we call *decoupled functional correctness* (DFC), which we have found leads to a substantially simpler logic, even while achieving this unprecedented combination of features. Precision is supported by reasoning about a program’s functional properties. However, the key insight of DFC is that this reasoning can and should be separated from reasoning about its information flow security. As we explain, DFC exploits compositional functional correctness as a common means to unify together reasoning about various security concerns.

We provide an overview of VERONICA in Section 2. Section 3 then describes the general security property that it enforces, and so formally defines the threat model. Section 4 describes the programming language over which VERONICA has been developed. Section 5 then describes the VERONICA logic, whose virtues are further demonstrated in Section 6. Section 7 considers related work before Section 8 concludes.

All results in this paper have been formalised and mechanically proved in the interactive theorem prover Isabelle/HOL [41]. Our Isabelle formalisation is available at <https://www.dropbox.com/s/m5eaqwkd8hort4/veronica.tar.gz?dl=0>.

## 2. An Overview of VERONICA

Before explaining VERONICA in detail, we first motivate the high level ideas that underpin it and how they work together to facilitate expressiveness and precision.

### 2.1. Decoupling Functional Correctness

Figure 1a depicts the data-flow architecture for a very simple, yet illustrative, example system. This example is inspired by a real world security-critical shared-memory concurrent program [10]. This example purposefully avoids some of VERONICA’s features (e.g. secret-dependent branching and runtime state-dependent declassification policies), which we will meet later in Section 6. Verifying it requires highly precise reasoning, and the security policy it enforces involves both data-dependent sensitivity and delimited release style declassification [42], features that until now have never been reconciled before.

The system comprises four threads, whose code appears in Figure 1 (simplified a little for presentation). The four threads make use of a shared buffer *buf* protected by a lock  $\ell$ , which also protects the shared flag variable *valid*. The top-middle thread (Figure 1c) copies data into the

shared buffer, from one of two input/output (IO) channels:  $\perp$  (a public channel whose contents is visible to the attacker) and  $\top$  (a private channel, not visible to the attacker). The right-top thread (Figure 1e) reads data from the shared buffer *buf* and copies it to an appropriate output buffer (either  $\perp buf$  for  $\perp$  data or  $\top buf$  for  $\top$  data) for further processing by the remaining two output threads.

Each of the bottom threads outputs from its respective output buffer to its respective channel; one for  $\top$  data (Figure 1b) and the other for  $\perp$  data (Figure 1d).

The decision of the top-middle thread (Figure 1c, line 2), whether to input from the  $\perp$  channel or the  $\top$  one, is dictated by the shared variable *inmode*. The *valid* variable (initially zero) is set to 1 by the top-middle thread once it has filled the *buf* variable, and is then tested by the top-right thread (Figure 1e, line 2) to ensure it doesn’t consume data from *buf* before the top-middle thread has written to *buf*.

The top-right thread’s decision (Figure 1e, line 3) about which output buffer it should copy the data in *buf* to is dictated by the *outmode* variable. When *outmode* indicates that the  $\top$  buffer  $\top buf$  should be used, the top-right thread additionally performs a signature check (via the *CK* function, lines 7–8) on the data to decide if it is safe to declassify and copy additionally to the  $\perp buf$  output buffer. This concurrent program implements a *delimited release* [42] style declassification policy, which states that  $\top$  data that passes the signature check, plus the results of the signature check itself for all  $\top$  data, are safe to declassify. The language of VERONICA includes the *declassifying assignment* command  $\hat{:=}$  and the *declassifying output* command  $!$ . Besides delimited release style declassification policies, we will see later in the examples of Section 6 that our security condition also supports stateful declassification policies.

Clearly, if *inmode* and *outmode* disagree, the concurrent execution of the threads might behave insecurely (e.g. the top-middle thread might place private  $\top$  data into *buf*, which the top-right thread then copies to  $\perp buf$  and is subsequently output on the public channel  $\perp$ ). Therefore, the security of this concurrent program rests on the shared data invariant that *inmode* and *outmode* agree (whenever lock  $\ell$  is acquired and released). This is a functional correctness property. There are a number of other such functional properties, somewhat more implicit, on which the system’s security relies, e.g. that neither thread will modify *buf* unless they hold the lock  $\ell$ , and likewise for *inmode* and *outmode*, plus that only one thread can hold the lock  $\ell$  at a time.

Similarly, the security of the declassification actions performed by the top-right thread rests on the fact that it only declassifies after successfully performing the signature check, in accordance with the delimited release policy.

Thus one cannot reason about the security of this concurrent program in the absence of functional correctness. However, one of the fundamental insights of VERONICA is that functional correctness reasoning should be *decoupled* from security reasoning. This is in contrast to many recent logics for concurrent information flow security, notably the COVERN logic of [10] and its antecedents [19], [29] as

(a) Data flows. Dotted lines denote declassification.

```
1 {A0} ⊤ ! ⊤ buf
```

(b) Outputting ⊤ data.

```
1 {A1} acquire(ℓ);
2 {A2} if inmode = 0
3   {A3} buf ← ⊥
4 else
5   {A4} buf ← ⊤
6 endif;
7 {A5} valid := 1;
8 {A6} release(ℓ)
```

(c) Reading data into a shared buffer.

```
1 {A7} ⊥ ! ⊥ buf
```

(d) Outputting ⊥ data.

```
1 {A8} acquire(ℓ);
2 {A9} if valid = 1
3   {A10} if outmode = 0
4     {A11} ⊥ buf := buf
5   else
6     {A12} ⊤ buf := buf;
7     {A13} d ≐ CK (⊤ buf);
8     {A14} if d = 0
9       {A15} ⊥ buf ≐ ⊤ buf
10    endif
11  endif
12 endif ;
13 {A16} release(ℓ)
```

(e) Copying data from a shared buffer, with declassification.

Figure 1: Co-operative Use of a Shared Buffer. The green  $\{A_i\}$  are functional correctness annotations whose contents we omit in the interests of brevity.

well as [30], [31] plus many prior logics for sequential programs [2], [5], [8], [9], [43], [44] and hardware designs [45].

VERONICA decouples functional correctness reasoning from security reasoning by performing the latter over programs that carry *functional correctness annotations*  $\{A_i\}$  on each program statement  $s_i$ . Thus program statements are of the form  $\{A_i\} s_i$ . Here,  $\{A_i\}$  should be thought of as akin to a Hoare logic precondition [46]. It states conditions that are known to be true whenever statement  $s_i$  is executed in the *concurrent* program. We call this resulting approach *decoupled functional correctness* (DFC).

The contents of each of the annotations in Figure 1c and Figure 1e have been omitted in the interests of brevity, and simply replaced by identifiers  $\{A_i\}$ . In reality<sup>1</sup>, annotation  $\{A_2\}$  in Figure 1c includes the fact that the thread holds the lock  $\ell$ ;  $\{A_3\}$  would imply that *inmode* is zero, while  $\{A_4\}$  would imply the opposite. Annotation  $\{A_5\}$  on the other hand tracks information about the contents of *buf*, namely if *inmode* is zero then *buf* holds the last input read from channel  $\perp$ , and it holds the last input read from channel  $\top$  otherwise<sup>2</sup>.

For the top-right thread, Figure 1e,  $\{A_{11}\}$  would imply that *buf* holds an input read from channel  $\perp$  (justifying why copying its contents to the  $\perp$  variable  $\perp buf$  is secure), and  $\{A_{12}\}$  would imply likewise for channel  $\top$ .  $\{A_{13}\}$  would imply that  $\top buf$  holds  $\top$  data and  $\{A_{14}\}$  that  $d$  holds the result of the signature check. Finally,  $\{A_{15}\}$  implies that the signature check passed, justifying why the declassifying assignment to  $\perp buf$  is secure.

Thus the annotations  $\{A_i\}$  afford highly precise reasoning about the security of each thread, while decoupling the functional correctness reasoning.

The idea of using annotations  $\{A_i\}$  we repurpose from the Owicki-Gries proof technique [47] for concurrent pro-

grams. Indeed, there exist a range of standard techniques for inferring and proving the soundness of such annotations (i.e. for carrying out the functional correctness reasoning), from the past 40 years of research on concurrent program verification. VERONICA integrates multiple such techniques in the Isabelle/HOL theorem prover, each of which has been proved sound from first principles, thereby ensuring the correctness of its foundations.

Given a correctly annotated program, VERONICA then exploits the functional correctness information encoded in the annotations to prove expressive security policies. We outline how in the next section.

## 2.2. Compositional Enforcement

How can we prove that the concurrent program of Figure 1 doesn't violate information flow security, i.e. that no  $\top$  data is leaked, unless it has been declassified in accordance with the delimited release policy?

Doing so in general benefits from having a compositional reasoning method, namely one that reasons over each of the program's threads separately to deduce that the concurrent execution of those threads is secure.

Compositional methods for proving information flow properties of concurrent programs have been studied for decades [20], [21]. Initial methods required one to prove that each thread was secure ignorant of the behaviour of other threads [20], [21], [24]. Such reasoning is sound but necessarily imprecise: for instance when reasoning about the top-middle thread (Figure 1c) we wouldn't be allowed to assume that the top-right thread (Figure 1e) adheres to the locking protocol that protects *buf*.

Following Mantel et al. [29], more modern compositional methods have adopted ideas from rely-guarantee reasoning [34] to allow more precise reasoning about each thread under assumptions it makes about the behaviour of others (e.g. correct locking discipline) [10], [19]. However, the precision of these methods comes at a number of costs.

1. The annotations are stated and verified in our Isabelle formalisation.  
2.  $\{A_5\}$  effectively encodes *buf*'s (state-dependent) sensitivity, and takes the place of dependent security types and labels from prior systems.

The first cost is expressiveness, specifically the inability of such methods to reason about declassification. The second is complexity, since these methods entangle security and functional correctness reasoning.

By *decoupling* functional correctness reasoning, VERONICA achieves both precision and expressiveness, while being simpler than existing techniques. This simplicity shows not only in the VERONICA logic (see Section 5) but also in its soundness proof, which is less than half the size of prior such proofs (see Section 5.3).

The VERONICA logic—VERONICA’s compositional IFC proof method—has judgements of the form  $lvl_A \vdash c$ , where  $lvl_A$  is a security level (e.g.  $\top$  or  $\perp$  in the case of Figure 1) representing level of the attacker and  $c$  is a fragment of program text (i.e. a program statement). This judgement holds if the program fragment  $c$  doesn’t leak information to level  $lvl_A$  that  $lvl_A$  should not be allowed to observe. For the code of each thread  $t$ , one uses the rules of VERONICA’s logic to prove that  $lvl_A \vdash c$  holds, where  $lvl_A$  ranges over all possible security levels. By doing so one establishes that the concurrent program is secure, under the assumption that the concurrent program is functionally correct (i.e. each of its annotations  $\{A_i\}$  hold when the concurrent program is executed). As mentioned, functional correctness can be proved using a range of well-established techniques that integrate into VERONICA.

Unlike recent compositional proof methods (c.f. [10], [19], [29]), the judgement of VERONICA has no need to track variable stability information (i.e. which variables won’t be modified by other threads), nor any need for a flow-sensitive typing context to track the sensitivity of data in shared program variables, nor does it track constraints on the values of program variables. Instead, this information is provided via the annotations  $\{A_i\}$ .

For example, the annotation  $\{A_{11}\}$  in Figure 1 (Figure 1e, line 4) states that: (1) when *valid* is 1, if *inmode* is 0 then *buf* contains the last input read from channel  $\perp$  and otherwise it contains the last  $\top$  input; (2) the top-right thread holds the lock  $\ell$ ; (3) *inmode* and *outmode* agree; and (4) *outmode* is 0 and *valid* is 1. Condition (1) implicitly encodes sensitivity information about the data in the shared variable *buf*; (2) encodes stability information; while (3) and (4) are constraints on shared program variables.

To prove that the assignment on line 4 of Figure 1e is secure, VERONICA requires one to show that the sensitivity of the data contained in *buf* is at most  $\perp$  (the level of  $\perp buf$ ). However one gets to assume that the annotation at this point  $\{A_{11}\}$  holds. In this case, the obligation is discharged straightforwardly from the annotation. The same is true for other parts of this concurrent program. In this way, VERONICA leans on the functional correctness annotations to establish security, and utilises compositional functional correctness to unify reasoning about various security concerns (e.g. declassification, state-dependent sensitivity, etc.).

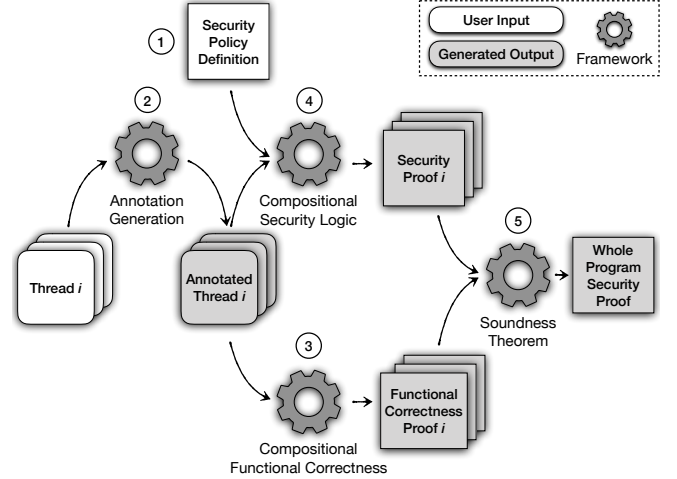

Figure 2: Proving a program secure in VERONICA.

### 2.3. Proving a Concurrent Program Secure

Figure 2 depicts the process of proving a concurrent program secure using VERONICA. The circled numbers indicate the main steps and their ordering.

**Step ①: Defining the Security Policy.** The first step is to define the security policy that is to be enforced. This involves two tasks. The first is to choose an appropriate lattice of security levels [48] and then to assign security levels to shared variables (e.g. in the example of Figure 1,  $\perp buf$  and  $d$  both have level  $\perp$ , while  $\top buf$  has level  $\top$ ). A variable’s security level is given by the (user supplied) function  $\mathcal{L}$ , which assigns levels to variables. For variable  $v$ ,  $\mathcal{L}(v)$  defines the maximum sensitivity of the data that  $v$  is allowed to hold at all times.

In VERONICA not all shared variables need be assigned a security level, meaning that  $\mathcal{L}$  is allowed to be a *partial* function. For instance, in the example of Figure 1, *buf* has no level assigned (i.e.  $\mathcal{L}(buf)$  is undefined). The security policy does not restrict the sensitivity of the data that such *unlabelled* variables are allowed to hold. This is useful for shared variables like *buf* that form the interface between two threads and whose sensitivity is governed by a data-dependent contract [10]. In the example, this allows *buf* (whenever *valid* is 1) to hold  $\perp$  data when *inmode* and *outmode* are both zero, and  $\top$  data when *inmode* and *outmode* are both nonzero.

The second part of defining the security policy is to specify when and how declassification is allowed to occur. In order to maximise expressiveness, VERONICA supports dynamic, state-dependent declassification policies. Such policies are encoded via the (user supplied) predicate  $\mathcal{D}$ . For a source security level  $lvl_{src}$  and destination security level  $lvl_{dst}$ , the program command  $c$  is allowed to declassify the  $lvl_{src}$ -sensitivity value  $v$  to level  $lvl_{dst}$  in system state  $\sigma$  precisely when  $\mathcal{D}(lvl_{src}, lvl_{dst}, \sigma, v, c)$  holds. Note that the command  $c$  is either a declassifying assignment “ $\{A_i\}$ ”

$x \hat{=} E$ ” (in which case  $lvl_{dst}$  is the label  $\mathcal{L}(x)$  assigned to the labelled variable  $x$ ) or a declassifying output “ $\{A_i\} lvl_{dst} \hat{=} E$ ”. In either case,  $lvl_{src}$  is the security level of the expression  $E$  and  $v$  is the result of evaluating  $E$  in state  $\sigma$ .

This style of declassification predicate is able to support various declassification policies, including delimited release style policies as in the example of Figure 1. We discuss precisely how delimited release policies are encoded as declassification predicates  $\mathcal{D}$  later in Section 3.4. Other declassification policies are encountered in Section 6.

**Step ②: Generate Annotations.** Having defined the security policy, the second step to proving a concurrent program secure using VERONICA is to generate the functional correctness annotations  $\{A_i\}$  for each thread. In the example of Figure 1, while their contents is not shown, these annotations are already present. However in practice, users of VERONICA will start with un-annotated programs for which functional correctness annotations  $\{A_i\}$  are then generated to decorate each program statement  $c$  of each thread, encoding what facts are believed to be true about the state of the concurrent program whenever statement  $c$  executes.

Note that, because these annotations will be verified later (in step ③), there is no need to trust the generation process. The current Isabelle incarnation of VERONICA includes a proof-of-concept strongest-postcondition style annotation inference algorithm, whose results sometimes need manual tweaking. Users are also free to employ external, automatic program analysis tools to infer functional correctness annotations, or to supply annotations manually, without fear of compromising the foundational guarantees of VERONICA.

**Step ③: Verifying Functional Correctness.** Having inferred the functional correctness annotations  $\{A_i\}$ , the next step is to *prove* their validity. This means proving that the concurrent program is functionally correct, for which there exist numerous compositional techniques [34], [47].

VERONICA incorporates two standard techniques: the Owicki-Gries method [47] and Rely-Guarantee reasoning [34]. VERONICA’s Owicki-Gries implementation is borrowed from the seminal work of Prensa Nieto [49], [50]. Using it to verify (correct) functional correctness annotations requires little effort for experienced Isabelle users, by guiding Isabelle’s proof automation tactics. Like VERONICA’s Owicki-Gries method, its Rely-Guarantee implementation is for verifying functional correctness annotations only, and ignores security (c.f. [19], [29]). It requires the user to supply *rely* and *guarantee* conditions for each thread. Such conditions can be defined straightforwardly from the locking protocol of a concurrent program and in principle could be inferred; however, we leave that inference for future work.

**Step ④: Verifying Security.** With functional correctness proved, the user is then free to use the functional correctness annotations to compositionally prove the security of the concurrent program. To do this, the user applies the rules of the VERONICA logic to each of the program’s threads. We defer a full presentation of the logic to Section 5.

**Step ⑤: Whole Program Security Proof.** With both functional correctness and security proved of each thread, the soundness theorem of the VERONICA logic can then be applied to derive a theorem stating that the whole concurrent program is secure. This theorem is stated formally in Section 5.3. However, intuitively it says that the whole concurrent program is secure if, for each thread  $t$ ,  $t$ ’s functional correctness annotations are all valid (i.e. each holds whenever the corresponding statement of  $t$  is executed in the concurrent program)—step ③—and  $t$  is judged secure by the rules of the VERONICA logic—step ④.

### 3. Security Definition

VERONICA proves an information flow security property designed to capture a range of different security policies. To maximise generality, the security property is phrased in a knowledge-based (or *epistemic*) style, which as others have argued [13], [14], [51], [52] is preferable to traditional two-run formulations. Before introducing the security property and motivating the threat model that it formally encodes, we first explain the semantic model of concurrent program execution in which the property is defined.

Along the way, we highlight the assumptions encoded in that semantic model and in the formal security property. Following Murray and van Oorschot [53], we distinguish *adversary expectations*, which are assumptions about the attacker (e.g. their observational powers); from *domain hypotheses*, which are assumptions about the environment (e.g. the scheduler) in which the concurrent program executes.

#### 3.1. Semantic Model

Concurrent programs comprise a finite collection of  $n$  threads, each of which is identified by a natural number:  $0, \dots, n-1$ . Threads synchronise by acquiring and releasing locks and communicate by modifying shared memory. Additionally, threads may communicate with the environment outside the concurrent program by inputting and outputting values from/to IO *channels*. Without loss of generality, there is one channel for each security level (drawn from the user-supplied lattice of security levels).

**Global States  $\sigma$ .** Formally, the *global states*  $\sigma$  of the concurrent program are tuples  $(env_\sigma, mem_\sigma, locks_\sigma, tr_\sigma)$ . The global state contains all resources that are shared between threads. We consider each in turn.

**Channels and the Environment  $env_\sigma$ .**  $env_\sigma$  captures the state of the external environment (i.e. the IO channels). For a security level  $lvl$ ,  $env_\sigma(lvl)$  is the (infinite) stream of values yet to be consumed from the channel  $lvl$  in state  $\sigma$ .

**Domain Hypothesis** In this model of channels, reading from a channel never blocks and always returns the next value to be consumed from the infinite stream. This effectively assumes that all channel inputs are faithfully buffered and never dropped by the environment. Blocking can be simulated by repeatedly polling a channel.

**Shared Memory**  $mem_\sigma$ .  $mem_\sigma$  is the shared memory (excluding locks), and is simply a total mapping from variable names to their corresponding values:  $mem_\sigma(v)$  denotes the value of variable  $v$  in state  $\sigma$ .

**Locks**  $locks_\sigma$ .  $locks_\sigma$  captures the lock state and is a partial function from lock names to thread ids (natural numbers in the range  $0 \dots n - 1$ ): for a lock  $\ell$ ,  $locks_\sigma(\ell)$  is defined iff lock  $\ell$  is currently held in state  $\sigma$ , in which case its value is the id of the thread that holds the lock.

**Events  $e$  and Traces  $tr_\sigma$** . For the sake of expressiveness, we store in the global state  $\sigma$  the entire history of events  $tr_\sigma$  that has been performed by the concurrent program up to this point. Each such history is called a *trace*, and is simply a finite list of events  $e$ . Events  $e$  comprise: *input* events  $\mathbf{in}\langle lwl, v \rangle$  which record that value  $v$  was input from the channel  $lwl$ ; *output* events  $\mathbf{out}\langle lwl, v, E \rangle$  which record that value  $v$ , the result of evaluating expression  $E$ , was output on channel  $lwl$ ; and *declassification* events  $\mathbf{d}\langle lwl, v, E \rangle$  which record that the value  $v$ , the result of evaluating expression  $E$ , was declassified to level  $lwl$ . Expression  $E$  is included to help specify the security property (see e.g. Definition 3.2.7).

Ordinary (non-declassifying) output and input commands produce output and input events respectively. Declassifying assignments and declassifying outputs produce declassification events. As with much prior work on declassification properties [54], declassification actions produce distinguished declassification events that make them directly visible to the security property.

**The Schedule**  $sched$ .

**Domain Hypothesis** VERONICA assumes deterministic, sequentially-consistent, instruction-based scheduling [55] (IBS) of threads against a fixed, public schedule.

The *schedule*  $sched$  is an infinite list (stream) of thread ids  $i$ . Scheduling occurs by removing the first item  $i$  from the stream and then executing the thread  $i$  for one step of execution. (Longer execution slices can of course be simulated by repeating  $i$  in the schedule.) This process is repeated *ad infinitum*. If thread  $i$  is stuck (e.g. because it is waiting on a lock or has terminated) then the system idles for an execution step, to mitigate scheduling leaks (e.g. as implemented in seL4 [56]).

**Global Configurations and Concurrent Execution**  $\cdot \rightarrow \cdot$ . A *global configuration* combines the shared global state  $\sigma$  with the schedule  $sched$  and the local state  $ls_i$  (the thread id and code) of each of the  $n$  threads. Thus a global configuration is a tuple:  $(ls_0, \dots, ls_{n-1}, \sigma, sched)$ .

Concurrent execution, and the aforementioned scheduling model, is formally defined by the rules of Figure 7 (relegated to the appendix for brevity). These rules define a single-step relation  $\cdot \rightarrow \cdot$  on global configurations. Zero- and multi-step execution is captured in the usual way by the reflexive, transitive closure of this relation, written  $\cdot \rightarrow^* \cdot$ .

## 3.2. System Security Property and Threat Model

With these ingredients we can now define the formal security property of VERONICA. In doing so we formalise the threat model and adversary expectations.

**Attacker Observations.**

**Adversary Expectation:** Our security property considers a passive attacker observing the execution of the concurrent program. We assume that the attacker is able to observe outputs on certain channels and associated declassification events. Specifically, the attacker is associated with a security level  $lwl_A$ . Outputs on all channels  $lwl \leq lwl_A$  the attacker is assumed to be able to observe. Likewise all declassifications to levels  $lwl \leq lwl_A$ . Otherwise the attacker has no other means to interact with the concurrent program, e.g. by modifying its code. We additionally assume that the attacker does not have access to timing information and so e.g. cannot observe the time between when outputs occur etc.

The attacker's observational powers are formalised by defining a series of indistinguishability relations as follows.

**Definition 3.2.1** (Event Visibility). *We say that an input event  $\mathbf{in}\langle lwl, v \rangle$  (respectively output event  $\mathbf{out}\langle lwl, v, E \rangle$  or declassification event  $\mathbf{d}\langle lwl, v, E \rangle$ ) is visible to the attacker at level  $lwl_A$  iff  $lwl \leq lwl_A$ . Letting  $e$  be the event, in this case we write  $visible_{lwl_A}(e)$ .*

Trace indistinguishability is then defined straightforwardly, noting that we write  $tr \upharpoonright P$  to denote filtering from trace  $tr$  all events that do not satisfy the predicate  $P$ .

**Definition 3.2.2** (Trace Indistinguishability). *We say that two traces  $tr$  and  $tr'$  are indistinguishable to the attacker at level  $lwl_A$ , when  $tr \upharpoonright visible_{lwl_A} = tr' \upharpoonright visible_{lwl_A}$ .*

*In this case, we write  $tr \overset{lwl_A}{\approx} tr'$ .*

**Attacker Knowledge of Initial Global State.** Besides defining what the attacker is assumed to observe (via the indistinguishability relation on traces), we also need to define what knowledge the attacker is assumed to have about the initial global state  $\sigma_{init}$  of the system.

**Adversary Expectation:** The attacker is assumed to know the contents that will be input from channels at levels  $lwl \leq lwl_A$  and the initial values of all labelled variables  $v$  for which  $\mathcal{L}(v) \leq lwl_A$ .

This assumption is captured via an indistinguishability relation on global states  $\sigma$ . This relation is defined by first defining indistinguishability relations on each of  $\sigma$ 's components.

**Definition 3.2.3** (Environment Indistinguishability). *We say that two environments  $env$  and  $env'$  are indistinguishable to the attacker at level  $lwl_A$  when all channels visible to the attacker have identical streams, i.e. iff*

$$\forall lwl \leq lwl_A. env(lwl) = env'(lwl).$$

In this case we write  $env \stackrel{lvl_A}{\approx} env'$ .

**Definition 3.2.4** (Memory Indistinguishability). We say that two memories  $mem$  and  $mem'$  are indistinguishable to the attacker at level  $lvl_A$  when they agree on the values of all labelled variables  $v$  visible to the attacker, i.e. iff

$$\forall v. \mathcal{L}(v) \leq lvl_A \implies mem(v) = mem'(v),$$

where  $\mathcal{L}(v) \leq lvl_A$  implies  $\mathcal{L}(v)$  is defined.

In this case, we write  $mem \stackrel{lvl_A}{\approx} mem'$ .

We can now define when two (initial) global states are indistinguishable to the attacker.

**Definition 3.2.5** (Global State Indistinguishability). We say that two global states  $\sigma$  and  $\sigma'$  are indistinguishable to the attacker at level  $lvl_A$  iff

$$\begin{aligned} env_\sigma \stackrel{lvl_A}{\approx} env_{\sigma'} \wedge mem_\sigma \stackrel{lvl_A}{\approx} mem_{\sigma'} \wedge \\ locks_\sigma = locks_{\sigma'} \wedge tr_\sigma \stackrel{lvl_A}{\approx} tr_{\sigma'} \end{aligned}$$

In this case we write  $\sigma \stackrel{lvl_A}{\approx} \sigma'$ .

**Domain Hypothesis** Under this definition, the attacker knows the entire initial lock state. Thus we assume that the initial lock state encodes no secret information.

**Attacker Knowledge from Observations.** Given the attacker's knowledge about the initial state  $\sigma_{init}$  and some observation arising from some trace  $tr$  being performed, we assume that the attacker will then attempt to refine their knowledge about  $\sigma_{init}$ .

**Adversary Expectation:** The attacker is assumed to know the schedule  $sched$  and the initial local state  $ls_i$  (i.e. the code and thread id  $i$ ) of each thread.

Given that information, of all the possible initial states from which  $\sigma_{init}$  might have been drawn, perhaps only a subset can give rise to the observation of  $tr$ . We assume the attacker will perform this kind of knowledge inference, which we formalise following the epistemic style [51].

To define the attacker's knowledge, we define the attacker's uncertainty about the initial state  $\sigma_{init}$  (i.e. the attacker's belief about the set of all initial states from which  $\sigma_{init}$  might have been drawn) given the initial schedule  $sched$  and local thread states  $ls_0, \dots, ls_{n-1}$ , and the trace  $tr$  that the attacker has observed. Writing simply  $ls$  to abbreviate the list  $ls_0, \dots, ls_{n-1}$ , we denote this  $uncertainty_{lvl_A}(ls, \sigma_{init}, sched, tr)$  and define it as follows.

**Definition 3.2.6** (Attacker Uncertainty). A global state  $\sigma$  belongs to the set  $uncertainty_{lvl_A}(ls, \sigma_{init}, sched, tr)$  iff it and  $\sigma_{init}$  are indistinguishable, given the attacker's knowledge about the initial state, and if  $\sigma$  can give rise to

a trace  $tr_{\sigma'}$  that is indistinguishable from  $tr$ . Formally,  $uncertainty_{lvl_A}(ls, \sigma_{init}, sched, tr)$  is the set of  $\sigma$  where

$$\begin{aligned} \sigma \stackrel{lvl_A}{\approx} \sigma_{init} \wedge \\ \exists ls' \sigma' sched'. (ls, \sigma, sched) \rightarrow^* (ls', \sigma', sched') \wedge \\ tr \stackrel{lvl_A}{\approx} tr_{\sigma'} \end{aligned}$$

**The Security Property.** Finally, we can define the security property. This requires roughly that the attacker's uncertainty can decrease (i.e. they can refine their knowledge) only when declassification events occur, and that all such events must respect the declassification policy encoded by  $\mathcal{D}$ . In other words, the guarantee provided by VERONICA under the threat model formalised herein is that:

**Security Guarantee:** The attacker is never able to learn any new information above what they knew initially, except from declassification events but those must always respect the user-supplied declassification policy.

This guarantee is formalised by defining a *gradual release-style* security property [51]. We first define when the occurrence of an event  $e$  is secure.

**Definition 3.2.7** (Event Occurrence Security). Consider an execution beginning in some initial configuration  $(ls, \sigma, sched)$  that has executed to the intermediate configuration  $(ls', \sigma', sched')$  from which the event  $e$  occurs. This occurrence is secure against the attacker at level  $lvl_A$ , written  $esec_{lvl_A}((ls, \sigma, sched), (ls', \sigma', sched'), e)$ , iff

- When  $e$  is a declassification event  $\mathbf{d}\langle lvl_{dst}, v, E \rangle$  visible to the attacker (i.e.  $lvl_{dst} \leq lvl_A$ ), then  $\mathcal{D}(\mathcal{L}(E), lvl_{dst}, \sigma', v, c)$  must hold, where  $c$  is the current program command whose execution produced  $e$  (i.e. the head program command of the currently executing thread in  $(ls', \sigma', sched')$ ). Here,  $\mathcal{L}(E)$  is defined when  $\mathcal{L}(v)$  is defined for all variables  $v$  mentioned in  $E$  and in that case is the least upper bound of all such  $\mathcal{L}(v)$ , and  $\mathcal{D}(\mathcal{L}(E), lvl_{dst}, \sigma', v, c)$  is false when  $\mathcal{L}(E)$  is not defined.
- Otherwise, if  $e$  is not a declassification event  $\mathbf{d}\langle lvl_{dst}, v, E \rangle$  that is visible to the attacker, then the attacker's uncertainty cannot decrease by observing it, i.e. we require that

$$\begin{aligned} uncertainty_{lvl_A}(ls, \sigma, sched, tr_{\sigma'}) \subseteq \\ uncertainty_{lvl_A}(ls, \sigma, sched, tr_{\sigma'} \cdot e) \end{aligned}$$

**Definition 3.2.8** (System Security). The concurrent program with initial local thread states  $ls = (ls_0, \dots, ls_{n-1})$  is secure against an attacker at level  $lvl_A$ , written  $syssec_{lvl_A}(ls)$ , iff, under all schedules  $sched$ , event occurrence security always holds during its execution from any initial starting state  $\sigma$ . Formally, we require that

$$\begin{aligned} \forall sched \sigma ls' \sigma' sched' ls'' \sigma'' sched'' e. \\ (ls, \sigma, sched) \rightarrow^* (ls', \sigma', sched') \wedge \\ (ls', \sigma', sched') \rightarrow (ls'', \sigma'', sched'') \wedge \\ tr_{\sigma''} = tr_{\sigma'} \cdot e \implies \\ esec_{lvl_A}((ls, \sigma, sched), (ls', \sigma', sched'), e) \end{aligned}$$

### 3.3. Discussion

As with other gradual release-style properties, ours does not directly constrain *what* information the attacker might learn when a declassification event occurs, but merely that those are the only events that can increase the attacker’s knowledge. This means that, of the four semantic principles of declassification identified by Sabelfeld and Sands [57], our definition satisfies all but *non-occlusion*: “the presence of declassifications cannot mask other covert information leaks” [57]. Consider the following single-threaded program.

```

1 {A17} if birthYear > 2000
2   {A18} ⊥! birthDay
3 else
4   {A19} ⊥! birthMonth
5 endif

```

Suppose the intent is to permit the unconditional release of a person’s day and month of birth, but not their birth year. A naive encoding in the declassification policy  $\mathcal{D}$  that checks whether the value being declassified is indeed either the value of *birthDay* or *birthMonth* would judge the above program as secure, when in fact it also leaks information about the *birthYear*.

Note also, since declassification events are directly visible to our security property, that programs that incorrectly declassify information but then never output it on a public channel can be judged by our security condition as insecure.

Finally, and crucially, note that our security condition allows for both *extensional* declassification policies, i.e. those that refer only to inputs and outputs of the program, as well as *intensional* policies that also refer to the program state. Section 6 demonstrates both kinds of policies. We now consider one class of extensional policies: delimited release.

### 3.4. Encoding Delimited Release Policies

The occlusion example demonstrates that programs that branch on secrets that are not allowed to be released and then perform declassifications under that secret context are likely to leak more information than that contained in the declassification events themselves, via implicit flows.

However, in the absence of such branching, our security condition can in fact place bounds on what information is released. Specifically, we show that it can soundly encode delimited release [42] policies as declassification predicates  $\mathcal{D}$  for programs that do not branch on secrets that are not allowed to be declassified to the attacker.

We define an extensional delimited release-style security condition and show how to instantiate the declassification predicates  $\mathcal{D}$  so that when system security (Definition 3.2.8) holds, then so does the delimited release condition.

**3.4.1. Formalising Delimited Release.** Delimited release [42] weakens traditional noninterference [33] by permitting certain secret information to be released to the attacker. Which secret information is allowed to be released

is defined in terms of a set of *escape hatches*: expressions that denote values that are allowed to be released.

Delimited release then strengthens the indistinguishability relation on the initial state to require that any two states related under this relation also agree on the values of the escape hatch expressions. One way to understand delimited release as a weakening of noninterference is to observe that, in changing the relation in this way, it is effectively encoding the assumption that the attacker might *already know* the secret information denoted by the escape hatch expressions.

To keep our formulation brief, we assume that the initial memory contains no secrets. Thus all secrets are contained only in the input streams (i.e. the program can obtain secrets only by inputting them from channels). Thus escape hatches denote values that are allowed to be released as functions on lists *vs* of inputs (to be) consumed from a channel.

A *delimited release* policy  $\mathcal{E}$  is a function that given source and destination security levels  $lvl_{src}$  and  $lvl_{dst}$  returns a set of escape hatches denoting the information that is allowed to be declassified from level  $lvl_{src}$  to level  $lvl_{dst}$ .

For example, to specify that the program is always allowed to declassify to  $\perp$  the average of the last five inputs read from the  $\top$  channel, one could define:

$$\mathcal{E}(\top, \perp) = \{\lambda vs. \text{if } len(vs) \geq 5 \text{ then } avg(\text{take}(5, rev(vs))) \text{ else } 0\},$$

where  $avg(xs)$  calculates the average of a list of values *xs*,  $take(n, xs)$  returns a new list containing the first *n* values from the list *xs*, and  $rev(xs)$  is the list reversal function.

To define delimited release, we need to define when two initial states  $\sigma$  agree under the escape hatches  $\mathcal{E}$ . Since escape hatches apply only to the streams contained in the environment  $env_\sigma$ , we define when two such environments agree under  $\mathcal{E}$ . As with the earlier indistinguishability relations, this agreement is defined relative to an attacker observing at level  $lvl_A$ , and requires that all escape hatches that yield values that the attacker is allowed to observe always evaluate identically under both environments.

**Definition 3.4.1** (Environment Agreement under  $\mathcal{E}$ ). *Two environments  $env$  and  $env'$  agree under the delimited release policy  $\mathcal{E}$  for an attacker at level  $lvl_A$ , written  $env \stackrel{lvl_A, \mathcal{E}}{\approx} env'$ , iff, for all levels  $lvl_{src}$  and all levels  $lvl_{dst} \leq lvl_A$ , and escape hatches  $h \in \mathcal{E}(lvl_{src}, lvl_{dst})$ ,  $h$  applied to any finite prefix of  $env(lvl_{src})$  yields the same value as when applied to an equal length prefix of  $env'(lvl_{src})$ .*

With this definition, we can define when two initial states  $\sigma$  and  $\sigma'$  agree for a delimited release policy  $\mathcal{E}$ . For brevity, the following definition is a slight simplification of the one in our Isabelle formalisation, which is more general because it considers arbitrary pairs of states in which some trace of events might have already been performed. See the appendix for the more general definition (Definition A.1).

**Definition 3.4.2** (State Agreement under  $\mathcal{E}$ ). *We say that two states  $\sigma$  and  $\sigma'$  agree under the delimited release policy  $\mathcal{E}$  for an attacker at level  $lvl_A$ , written  $\sigma \stackrel{lvl_A, \mathcal{E}}{\approx} \sigma'$ ,*

iff (1)  $\sigma \stackrel{lvl_A}{\approx} \sigma'$ , (2) their memories agree on all variables, and (3)  $env_\sigma \stackrel{lvl_A, \mathcal{E}}{\approx} env_{\sigma'}$ .

Here, condition (2) encodes the simplifying assumption that the initial memories contain no secrets.

Delimited release is then defined straightforwardly in the style of a traditional two-run noninterference property. Note that this property is purely extensional.

**Definition 3.4.3** (Delimited Release). *The concurrent program with initial local thread states  $ls = (ls_0, \dots, ls_{n-1})$  satisfies delimited release against an attacker at level  $lvl_A$ , written  $drsec_{lvl_A}(ls)$ , iff,*

$$\begin{aligned} &\forall sched \ \sigma \ \sigma' \ y. \\ &\sigma \stackrel{lvl_A, \mathcal{E}}{\approx} \sigma' \wedge (ls, \sigma, sched) \rightarrow^* y \implies \\ &(\exists y'. (ls, \sigma', sched) \rightarrow^* y' \wedge tr_y \stackrel{lvl_A}{\approx} tr_{y'}) \end{aligned}$$

where for a global configuration  $y = (ls_y, \sigma_y, sched_y)$  we write  $tr_y$  to abbreviate  $tr_{\sigma_y}$ , the trace executed so far.

**3.4.2. Encoding Delimited Release in  $\mathcal{D}$ .** We now show how to encode delimited release policies  $\mathcal{E}$  via VERONICA's declassification predicates  $\mathcal{D}(lvl_{src}, lvl_{dst}, \sigma, v, c)$  which, recall, judge whether command  $c$  declassifying value  $v$  from level  $lvl_{src}$  to level  $lvl_{dst}$  in state  $\sigma$  is permitted. Recall that  $c$  is either a declassifying assignment “ $\{A_i\} x \hat{=} E$ ” (in which case  $lvl_{dst}$  is the label  $\mathcal{L}(x)$  assigned to the labelled variable  $x$ ) or a declassifying output “ $\{A_i\} lvl_{dst} \hat{!} E$ ”. In either case,  $lvl_{src}$  is the security level of the expression  $E$  and  $v$  is the result of evaluating  $E$  in state  $\sigma$ .

To encode delimited release, we need to have  $\mathcal{D}(lvl_{src}, lvl_{dst}, \sigma, v, c)$  decide whether there is an escape hatch  $h \in \mathcal{E}(lvl_{src}, lvl_{dst})$  that permits the declassification. Consider some  $h \in \mathcal{E}(lvl_{src}, lvl_{dst})$ . What does it mean for  $h$  to permit the declassification? Perhaps surprisingly, it is *not enough* to check whether  $h$  evaluates to the value  $v$  being declassified in  $\sigma$ . Suppose  $h$  permits declassifying the average of the last five inputs from channel  $\top$  and suppose in  $\sigma$  that this average is 42. An insecure program might declassify some *other* secret whose value just happens to be 42 in  $\sigma$ , but that declassification would be unlikely to satisfy delimited release if the two secrets are independent.

Instead, to soundly encode delimited release, one needs to check whether the expression  $E$  being declassified is equal to the escape hatch *in general*, and not just in the particular  $\sigma$  in which  $\mathcal{D}$  is being checked.

To do this we make use of VERONICA's chief properties: decoupled noninterference—in the form of the program annotations  $\{A_i\}$ —and its expressive security condition—via the ample information provided to  $\mathcal{D}$ . We have  $\mathcal{D}$  check that in all states in which this declassification  $c$  might be performed, the escape hatch  $h$  evaluates to the value of  $E$  in that state. We can overapproximate the set of all states in which the declassifying command  $c$  might execute by using its annotation: all such states must satisfy the annotation under the assumption that the concurrent program is functionally correct (which indeed will be formally proved

by VERONICA). Thus we have  $\mathcal{D}$  check that in all such states that satisfy the annotation, the escape hatch  $h$  evaluates to the expression  $E$ .

**Definition 3.4.4** (Delimited Release Encoding). *The encoding of a delimited release policy  $\mathcal{E}$  via declassification predicates  $\mathcal{D}$  we denote  $\mathcal{D}_{\mathcal{E}}$ .  $\mathcal{D}_{\mathcal{E}}(lvl_{src}, lvl_{dst}, \sigma, v, c)$  holds always when  $c$  is not a declassification command. Otherwise, let  $A$  be  $c$ 's annotation and  $E$  be the expression that  $c$  declassifies. Then  $\mathcal{D}_{\mathcal{E}}(lvl_{src}, lvl_{dst}, \sigma, v, c)$  holds iff there exists some  $h \in \mathcal{E}(lvl_{src}, lvl_{dst})$  such that for all states  $\sigma'$  that satisfy the annotation  $A$ ,  $E$  evaluates in  $\sigma'$  to the same value that  $h$  evaluates to when applied to the  $lvl_{src}$  inputs consumed so far in  $\sigma'$ .*

Recall that this encoding is sound only for programs that do not branch on secrets that the delimited release policy  $\mathcal{E}$  forbids from releasing. We define this condition semantically as a two-run property, relegating its description to Definition A.2 in the appendix for the sake of brevity, since its meaning is intuitively clear. We say that a program satisfying this condition is *free of  $\mathcal{E}$ -secret branching*.

The example of Section 3.3 that leaks *birthYear* via occlusion is not free of  $\mathcal{E}$ -secret branching. On the other hand, the program in Figure 1 is free of  $\mathcal{E}$ -secret branching for the following  $\mathcal{E}$  that defines its delimited release policy, since the only  $\top$ -value ever branched on (in Figure 1e, line 8) is the result of the signature check  $CK$ .

**Definition 3.4.5** (Delimited Release policy for Figure 1). *The delimited release policy for the program in Figure 1 allows the results of the signature check  $CK$  to be declassified to  $\perp$  and, when  $CK(v)$  returns zero for some  $\top$ -input  $v$ , allows  $v$  to be declassified to  $\perp$ .*

$$\begin{aligned} \mathcal{E}(\top, \perp) = & \\ & \{\lambda vs. \text{if } len(vs) \neq 0 \text{ then } CK(last(vs)) \text{ else } 0\} \cup \\ & \{\lambda vs. \text{if } len(vs) \neq 0 \wedge CK(last(vs)) = 0 \text{ then } \\ & \quad last(vs) \text{ else } 0\} \end{aligned}$$

Indeed, VERONICA can be used to prove that Figure 1 satisfies this delimited release policy by showing that it satisfies VERONICA's system security (Definition 3.2.8), under the following theorem that formally justifies why VERONICA can encode delimited release policies.

**Theorem 3.4.1** (Delimited Release Embedding). *Let  $lvl_A$  be an arbitrary security level and  $ls$  be the initial local thread states (i.e. thread ids and the code) of a concurrent program that (1) satisfies  $syssec_{lvl_A}(ls)$  with  $\mathcal{D}$  defined according to Definition 3.4.4, (2) is free of  $\mathcal{E}$ -secret branching, and (3) satisfies all of its functional correctness annotations. Then, the program is delimited release secure, i.e.  $drsec_{lvl_A}(ls)$ .*

Thus VERONICA can soundly encode purely extensional security properties like Definition 3.4.3, via declassification predicates  $\mathcal{D}$  that (perhaps surprisingly) refer to internal program state (e.g. the commands  $c$ ).

For the example of Figure 1 and its delimited release policy (Definition 3.4.5), one can simply unfold Definition 3.4.3 to arrive at a purely extensional characterisation of its secu-

$c ::= \{A\} x := E$	(assignment)
$\{A\} x \widehat{=} E$	(declassifying assignment)
$\{A\} lwl! E$	(output to channel $lwl$ )
$\{A\} lwl \widehat{!} E$	(declassifying output)
$\{A\} x \leftarrow lwl$	(input from channel $lwl$ )
$\{A\} \text{if } E \ c \ \text{else } c \ \text{endif}$	(conditional)
$\{A\} \text{while } E \ \text{inv } \{A\} \ \text{do } c$	(loop with invariant)
$\{A\} \text{acquire}(\ell)$	(lock acquisition)
$\{A\} \text{release}(\ell)$	(lock release)
$c; c$	(sequencing)
<b>stop</b>	(terminated thread)

Figure 3: Syntax of VERONICA threads.

ity policy. Doing so is straightforward, so we relegate the formal statement to [Definition A.3](#) in the appendix.

## 4. Annotated Programs in VERONICA

VERONICA reasons about the security of concurrent programs, each of whose threads is programmed in the language whose grammar is given in [Figure 3](#).

Most of these commands are straightforward and we have seen many of them already in [Figure 1](#). Loops “ $\{A\} \text{while } E \ \text{inv } \{I\} \ \text{do } c$ ” carry a second *invariant* annotation (here “ $\{I\}$ ”) that specifies the loop invariant, which is key for proving the functional correctness of loops [58]. The “**stop**” command halts the execution of the thread, and is not meant to be used in the surface syntax of threads (instead being an internal form used to define the semantics of the language). The *no-op* command “ $\{A\} \text{nop}$ ” is syntactic sugar for a command that does nothing: “ $\{A\} x := x$ ”, while the one-armed conditional “ $\{A\} \text{if } E \ c \ \text{endif}$ ” is syntactic sugar for “ $\{A\} \text{if } E \ c \ \text{else } \{A\} \ \text{nop} \ \text{endif}$ ”.

The semantics for this sequential language is given in [Figure 8](#), and is relegated to the appendix since it is straightforward. This semantics is defined as a small step relation on *local configurations*  $(ls_i, \sigma)$  where  $ls_i = (i, c)$  is the local state (thread id  $i$  and code  $c$ ) for a thread and  $\sigma = (env_\sigma, mem_\sigma, locks_\sigma, tr_\sigma)$  is the global state shared with all other threads. Notice that the semantics doesn’t make use of the annotations  $\{A\}$ : annotations are merely decorations used to decouple functional correctness.

## 5. The VERONICA Logic

The VERONICA logic defines a compositional method to prove when a concurrent program satisfies system security ([Definition 3.2.8](#)), VERONICA’s security condition. Specifically, it defines a set of rules for reasoning over the program text of each thread of the concurrent program. A soundness theorem ([Theorem 5.3.1](#)) guarantees that programs that are functionally correct and whose threads are proved secure using the VERONICA logic satisfy system security.

The rules of the VERONICA logic appear in [Figure 4](#). They define a judgement resembling that for a flow-insensitive security type system that has the following form,

$$lwl_A \vdash c$$

where  $lwl_A$  is the attacker level and  $c$  is an annotated thread command (see [Figure 3](#)).

### 5.1. Precise Reasoning with Annotations

The rules for VERONICA explicitly make use of the annotations  $\{A\}$  on program commands to achieve highly precise reasoning, while still presenting a simple logic to the user. This is evident in the simplicity of many of the rules of [Figure 4](#). To understand how annotations are used to achieve precise reasoning, consider the rule OUTTY for outputting on channel  $lwl$ . When this output is visible to the attacker ( $lwl \leq lwl_A$ ), this rule uses the annotation  $A$  to reason about the sensitivity of the data contained in the expression  $E$  at this point in the program, specifically to check that this sensitivity is no higher than the attacker level  $lwl_A$ . This is captured by the predicate  $sensitivity(A, E, lwl_A)$ .

In particular, for a security level  $lwl$ , annotation  $A$  and expression  $E$ ,  $sensitivity(A, E, lwl)$  holds when, under annotation  $A$ , the sensitivity of the data contained in expression  $E$  is not greater than  $lwl$ . Note that this is *not* a policy statement about  $\mathcal{L}(E)$  but, instead, a statement about  $E$ ’s sensitivity at this point during the program’s execution as over-approximated by the annotation  $A$ . It is defined as:

$$\begin{aligned} sensitivity(A, E, lwl) &\equiv \forall \sigma \ \sigma'. \ \sigma \models A \wedge \sigma' \models A \wedge \sigma \stackrel{lwl}{\approx} \sigma' \\ &\implies \lfloor E \rfloor_{mem_\sigma} = \lfloor E \rfloor_{mem_{\sigma'}} \end{aligned}$$

In a similar manner, the rules DASGTy and DOUTTY for reasoning about declassification use the annotation  $A$  to reason precisely about whether  $\mathcal{D}$  holds at this point during the program, as reflected in their premises.

### 5.2. Secret-Dependent Branching

The final premise of the rule IFTY for reasoning about conditionals “ $\{A\} \text{if } E \ c_1 \ \text{else } c_2 \ \text{endif}$ ” requires proving that the two branches  $c_1$  and  $c_2$  are  $lwl_A$ -bisimilar if the sensitivity of the condition  $E$  exceeds that which can be observed by the attacker  $lwl_A$ . In this case, the if-condition has branched on a secret that should not be revealed to the attacker. The program will be secure only when the attacker cannot distinguish the execution of  $c_1$  from the execution of  $c_2$ . This is the intuition of what it means for the two commands to be  $lwl_A$ -bisimilar, whose formal definition ([Definition A.7](#)) appears in the appendix.

VERONICA includes a set of proof rules to determine whether two commands are  $lwl_A$ -bisimilar. These rules have been proved sound but, due to lack of space, we refer the reader to our Isabelle formalisation for the full details. Briefly, these rules check that both commands (1) perform the same number of execution steps, (2) modify no labelled variables  $x$  for which  $\mathcal{L}(x) \leq lwl_A$ , (3) never input from

$$\begin{array}{c}
\frac{}{wl_A \vdash \mathbf{stop}} \text{STOPTY} \qquad \frac{}{wl_A \vdash \{A\} \mathbf{acquire}(\ell)} \text{ACQTY} \qquad \frac{}{wl_A \vdash \{A\} \mathbf{release}(\ell)} \text{RELY} \\
\frac{wl_A \vdash c_1 \quad wl_A \vdash c_2}{wl_A \vdash c_1; c_2} \text{SEQTY} \qquad \frac{\mathcal{L}(x) \text{ is undefined}}{wl_A \vdash \{A\} x := E} \text{UASGTY} \qquad \frac{\text{sensitivity}(A, E, wl_E) \quad wl_E \leq \mathcal{L}(x)}{wl_A \vdash \{A\} x := E} \text{LASGTY} \\
\frac{\forall \sigma. \sigma \models A \implies \mathcal{D}(\mathcal{L}(E), \mathcal{L}(x), \sigma, \lfloor E \rfloor_{\text{mem}_\sigma}, \{A\} x \hat{=} E)}{wl_A \vdash \{A\} x \hat{=} E} \text{DASGTY} \\
\frac{\forall \sigma. \sigma \models A \implies \mathcal{D}(\mathcal{L}(E), wl, \sigma, \lfloor E \rfloor_{\text{mem}_\sigma}, \{A\} wl \hat{=} E)}{wl_A \vdash \{A\} wl \hat{=} E} \text{DOUTTY} \\

\end{array}$$

Figure 4: Rules of the VERONICA logic.

or output to channels  $wl \leq wl_A$ , and (4) perform no declassifications. Thus the  $wl_A$ -attacker cannot tell which command was executed, including via scheduling effects.

One is of course free to implement other analyses to determine bisimilarity. Hence, VERONICA provides a modular interface for reasoning about secret-dependent branching.

### 5.3. Soundness

Recall that the soundness theorem requires the concurrent program (with initial thread states)  $ls = (ls_0, \dots, ls_{n-1})$  to satisfy all of its functional correctness annotations. When this is the case we write  $\models ls$ .

**Theorem 5.3.1** (Soundness). *Let  $ls = ((0, c_0), \dots, (n-1, c_{n-1}))$  be the initial local thread states of a concurrent program. If  $\models ls$  holds and  $wl_A \vdash c_i$  holds for all  $0 \leq i < n$ , then the program satisfies system security, i.e.  $\text{syssec}_{wl_A}(ls)$ .*

In practice one applies the VERONICA logic for an arbitrary attacker security level  $wl_A$ , meaning that system security will hold for attackers at all security levels.

The condition  $\models ls$  can of course be discharged using any of the techniques implemented in VERONICA, as described in Section 2.3 (Step ③), or by applying any other sound functional correctness verification method.

Decoupling functional correctness not only makes VERONICA far simpler than contemporary logics like COVERN [10], but also greatly simplifies its proof of soundness. For example, the publicly available COVERN soundness proof is around 6,500 lines of Isabelle/HOL whereas the soundness proof for VERONICA comprises about 2,700 lines

of Isabelle/HOL. Proof line count is known to be strongly correlated to proof effort [59]. A further comparison between VERONICA and COVERN is in Section 6.4.

## 6. Further Examples

### 6.1. The Example of Figure 1

Recall that the concurrent program of Figure 1 implements an extensional delimited release style policy  $\mathcal{E}$  defined in Definition 3.4.5 (see also Definition A.3 in the appendix).

We add a fifth thread, which toggles *inmode* and *outmode* while ensuring they agree. It also sets *valid* to zero, since *inmode* and *outmode* can no longer be relied upon (e.g. by the top-right thread of Figure 1) to judge the sensitivity of *buf*'s contents.

```

1 {A20} acquire(ℓ);
2 {A21} valid := 0;
3 {A22} inmode := inmode + 1;
4 {A23} outmode := inmode;
5 {A24} release(ℓ)

```

Proving that this 5-thread program  $ls$  satisfies this policy is relatively straightforward using VERONICA. We employ VERONICA's Owicki-Gries implementation to prove that it satisfies its annotations:  $\models ls$ . We then use the delimited release encoding (Definition 3.4.4) to generate the VERONICA declassification policy  $\mathcal{D}$  that encodes the delimited release policy. Next, we use the rules of the VERONICA logic to compositionally prove that each thread  $ls_i$  is secure for an arbitrary security level  $wl$ :  $wl \vdash ls_i$ . From this proof, since we never use the part of the IFTY rule for

branching on secrets, it follows that the program is free of  $\mathcal{E}$ -secret branching (we prove this result in general in our Isabelle formalisation). Then, by the soundness theorem (Theorem 5.3.1) the program satisfies VERONICA’s system security property  $syssec_{lwl}(ls)$  for arbitrary  $lwl$ . Finally, by the delimited release embedding theorem (Theorem 3.4.1) it satisfies its delimited release policy  $\mathcal{E}$ .

The proof, including defining the program, security lattice and the extensional delimited release policy, is 405 lines of Isabelle/HOL (128 definitions, 277 proofs), including some rudimentary custom automation [60].

## 6.2. Confirmed Declassification

Besides delimited release-style policies, VERONICA is geared to verifying state-dependent declassification policies. Such policies are common in systems in which interactions with trusted users authorise declassification decisions. For example, in a sandboxed desktop operating system like Qubes OS [61], a user can copy sensitive files from a protected domain into a less protected one, via an explicit dialogue that requires the user to *confirm* the release of the sensitive information. Indeed, user interactions to make explicit (e.g. “Application X wants permission to access your microphone...”) or implicit [62] information access decisions are common in modern computer systems. Yet being able to verify that concurrent programs only allow information access after successful user confirmation has remained out of reach for prior logics. We show how VERONICA can support such policies by considering a modification to the example program of Figure 1.

Specifically, suppose the thread in Figure 1e is replaced by the one in Figure 5. Instead of using the signature check function  $CK$  to decide whether to declassify the  $\top$  input, it now asks the user by first outputting the value to be declassified on channel  $\top$  and then receiving from the user a boolean response on channel  $\perp$ . This protocol effectively asks the user: “Is *this*  $\top$ -value the one you want to declassify?”

Naturally the user is trusted, so it is appropriate for their response to this question to be received on the  $\perp$  channel. Recall that  $\perp$  here means that the information has minimal secrecy, not minimal integrity. Indeed, since the user is trusted and the threat model of Section 3.2 forbids the attacker from supplying channel inputs, we can trust the integrity of this response.

The declassification policy is then specified as a VERONICA runtime state-dependent declassification predicate  $\mathcal{D}$ . This predicate specifies that at all times, the most recent output sent (to the user to confirm) on the  $\top$  channel is allowed to be declassified precisely when the most recent input consumed from the  $\perp$  channel is 1.

$$\mathcal{D}(lwl_{src}, lwl_{dst}, \sigma, v, E) = (v = lastoutput(\top, \sigma) \wedge lastinput(\perp, \sigma) = 1)$$

Concretely, the policy satisfied by this program is then that attacker uncertainty can never decrease except through

```

1 {A25} acquire( $\ell$ );
2 {A26} if valid = 1
3   {A27} if outmode = 0
4     {A28}  $\perp$ buf := buf
5   else
6     {A29}  $\top$ buf := buf;
7     {A30}  $\top$ !buf;
8     {A31} answer  $\leftarrow$   $\perp$ ;
9     {A32} if answer = 1
10      {A33}  $\perp$ buf  $\hat{=}$   $\top$ buf
11    endif
12  endif
13 endif ;
14 {A34} release( $\ell$ )

```

Figure 5: User-confirmed declassification.

declassification events. Additionally, any such declassification event must have been preceded by an output of the value  $v$  being declassified on the  $\top$  channel and confirmed by the user over the  $\perp$  channel. A complete formal statement of this policy is relegated to Definition A.4 in the appendix, since it is a trivial (yet quite verbose) unfolding of Definition 3.2.8 with  $\mathcal{D}$  as defined above. We note that the resulting property is purely extensional, which can be seen trivially since  $\mathcal{D}$  above refers only to the program’s input/output behaviour.

Proving the modified concurrent program secure proceeds similarly as for Section 6.1; the proof is about the same size (134 lines definitions, 236 lines proofs).

This example aptly demonstrates VERONICA’s advantages over contemporary logics like COVERN [10], which cannot handle declassification. Specifically, this example mimics the software functionality of the Cross Domain Desktop Compositor [63] (CDDC), which was recently verified with COVERN [10], but—crucially—includes the addition of the CDDC’s confirmed-cut-and-paste declassification functionality, which is out of reach for COVERN to verify.

## 6.3. Running Average

As a final example of stateful declassification and thread interaction, consider the concurrent program in Figure 6. The top-left inputs  $\top$ -sensitive numbers into the ( $\top$ -labelled) variable  $buf$  and keeps a running sum of the values seen so far in the ( $\top$ -labelled) variable  $sum$ , as well as counting the number of such values consumed in the ( $\perp$ -labelled) variable  $cnt$ . The security policy allows the average of the  $\top$  inputs consumed to be declassified so long as the program has consumed more inputs than whatever *threshold* is stored in the ( $\perp$ -labelled) variable  $min$ .

$$\mathcal{D}(lwl_{src}, lwl_{dst}, \sigma, v, E) = \text{if } len(inputs(\top, \sigma)) \geq mem_{\sigma}(min) \text{ then } v = avg(inputs(\top, \sigma)) \text{ else false}$$

Here the function  $inputs(lwl, \sigma)$  extracts from  $tr_{\sigma}$  all inputs consumed so far on channel  $lwl$ .

```

1 {A35} acquire(lavg);
2 {A36} buf ← ⊤;
3 {A37} cnt := cnt + 1;
4 {A38} sum := sum + buf;
5 {A39} release(lavg)
(a) Computing a running sum.

1 {A40} acquire(lmin);
2 {A41} min := min + 1;
3 {A42} release(lmin)
(b) Increasing the minimum threshold.

1 {A43} acquire(lavg);
2 {A44} acquire(lmin);
3 {A45} if cnt > min
4   {A46} if cnt > 0
5     {A47} ⊥!(sum/cnt)
6   endif
7 endif ;
8 {A48} release(lmin);
9 {A49} release(lavg)
(c) Declassifying the average.

```

Figure 6: Declassifying the average with dynamic threshold.

The threshold  $min$  can be changed, and this is what the bottom-left thread does by incrementing it. The right thread performs the declassification.

Thus this system implements a dynamic declassification policy whose enforcement requires careful coordination between the three threads. Its proof is similar in size to the earlier examples (116 lines definitions, 313 lines proofs).

In contrast to the previous two examples, the declassification policy of this example refers to internal program state (the variable  $min$ ). This style of policy cannot be expressed by a purely extensional property, unlike the prior examples. Our Isabelle formalisation contains a modified version of this example that satisfies an extensional policy in which the dynamic threshold is given by the  $\perp$  inputs received.

#### 6.4. A Comparison to COVERN

Finally, we compare VERONICA directly to the recent COVERN logic [10]. VERONICA is more expressive than COVERN, which cannot reason about declassification. As noted in Section 5, VERONICA’s logic and its soundness proof are also arguably simpler than those of COVERN.

In the absence of declassification VERONICA can verify programs for which COVERN is too restrictive. For example, even if declassification is removed from the example system of Section 6.1, COVERN’s rules for reasoning about variable assignments prevent it from proving that the assignment to *valid* by the toggle thread is secure.

On the other hand, systems that are straightforward to verify in COVERN can require more effort to verify in VERONICA. Such an example is depicted in Figure 9 in the appendix. It is essentially the example of Section 6.1 with declassification and the *valid* variable removed.

Verifying this system in COVERN took us around 90 minutes, including specifying the program and its security policy via COVERN’s *relational invariants*, and then completing the proof (294 lines definitions, 202 lines proofs).

In contrast, verifying this system in VERONICA (150 lines definitions, 422 lines proofs) required the addition of a *ghost variable*, called *GHOST* in Figure 9, which is not needed in COVERN. The *GHOST* variable is not a real program variable: none of the threads ever read its value.

Instead it is used to facilitate encoding of a suitable analogue of the COVERN relational invariant via the VERONICA program annotations (see Figure 9).

The need to sometimes introduce ghost variables when applying annotation-based concurrent program verification methods like Owicki-Gries [47] is well known [64]. VERONICA’s DFC approach naturally inherits this need.

Introducing such variables requires human insight and creativity. While the degree of effort is therefore difficult to predict in general, in this case it took us about an hour to realise that the ghost variable was necessary, and then another 30 minutes to introduce it and then complete the security proofs. Subsequently verifying the annotations was straightforward, although care was required here to guide Isabelle’s automated proof tactics. Overall, VERONICA required more effort to verify this example than COVERN.

## 7. Related Work

VERONICA targets compositional and precise verification of expressive forms of information flow security for shared-memory concurrent programs, by decoupled functional correctness (DFC). Prior techniques typically trade precision for expressiveness or vice-versa, or depart from realistic attacker models altogether [65].

The COVERN logic we have discussed already throughout (see Section 6.4): it trades expressiveness for precision.

Karbyshev et al. [28] present a highly precise separation logic based method for compositionally proving security of concurrent programs. Unlike VERONICA, their approach supports a far more flexible scheduler model, including reasoning about benign races on public variables, dynamic thread creation and thread→scheduler interactions. Unlike VERONICA, [28] doesn’t support declassification.

Others have examined information flow verification for *distributed* concurrent programs, in which threads do not share memory. Bauereiß et al. [27] present a method for verifying the security of such programs, including for some declassification policies and apply it to verify the key functionality of a distributed social media platform. Li et al. [32] present a rely-guarantee based method, tailored to systems in which the *presence* of messages on a channel can reveal sensitive information. In VERONICA, input is always assumed to be available on all channels.

Decoupled functional correctness was foreshadowed in the recent work of Li and Zhang [66] (as well as in aspects of Amtoft et al. [7]). Li and Zhang’s approach supports relatively precise reasoning about data-dependent sensitivity of sequential (i.e. non-concurrent) programs that carry annotations on assignment statements. VERONICA extends this idea across the entire program and applies it to compositional reasoning about shared-memory concurrent programs.

*Relational decomposition* [67], [68] and the *product program* approaches [69]–[71] encode security reasoning via functional correctness. Instead VERONICA exploits compositional functional correctness to aid security reasoning.

## 8. Conclusion

We presented VERONICA, the first compositional method for verifying information flow security for shared-memory concurrent programs that supports precise reasoning about expressive security policies. VERONICA embodies a new approach to building such logics, called decoupled functional correctness. This approach leads to a much simpler yet far more powerful logic than contemporaries.

As we demonstrated, VERONICA supports reasoning about myriad security policies, including delimited release-style declassification, value-dependent sensitivity and runtime-state dependent declassification, and their cooperative enforcement via non-trivial thread interactions.

The need for powerful methods to verify concurrent programs against non-trivial information security policies is more critical than ever. VERONICA sets a new standard for what should be expected of these methods.

## Appendix

### 1. Ancillary Definitions

**Definition A.1** (State Agreement under  $\mathcal{E}$  (full definition)). *We say that two states  $\sigma$  and  $\sigma'$  agree under the delimited release policy  $\mathcal{E}$  for an attacker at level  $lvl_A$ , written  $\sigma \stackrel{lvl_A, \mathcal{E}}{\approx} \sigma'$ , iff (1)  $\sigma \stackrel{lvl_A}{\approx} \sigma$ , (2) their memories agree on all variables, (3) the same number of inputs has been consumed so far in each, and (4) the environment obtained by appending the inputs consumed so far in  $\sigma$  to  $env_\sigma$  agrees under  $\mathcal{E}$  with the environment obtained by doing likewise to  $\sigma'$ .*

Here, condition (2) encodes the simplifying assumption that the initial memories contain no secrets. Conditions (3) and (4) are more complicated than might be expected due to having generalised over all  $\sigma$ : for initial states  $\sigma$  and  $\sigma'$  in which no events have been performed (i.e.  $tr_\sigma$  and  $tr_{\sigma'}$  are both empty), condition (3) holds trivially and condition (4) collapses to  $env_\sigma \stackrel{lvl_A, \mathcal{E}}{\approx} env_{\sigma'}$ : agreement of the two environments under  $\mathcal{E}$ . In this way this more general definition is morally equivalent to the simpler one (Definition 3.4.2) of Section 3.4.

**Definition A.2** (Absence of  $\mathcal{E}$ -Secret Branching). *We say that a program  $ls$  doesn’t branch on secrets that the delimited release policy  $\mathcal{E}$  forbids from releasing, when observed by an attacker at level  $lvl_A$ , when if for all schedules  $sched$  and initial states  $\sigma$ , if the program executes to some configuration  $y$ , then that execution can be matched from any other initial state  $\sigma'$  for which  $\sigma \stackrel{lvl_A, \mathcal{E}}{\approx} \sigma'$  to reach a configuration  $y'$  whose thread local states  $ls_{y'}$  is equal to  $ls_y$ , the thread local states of  $y$  (meaning that the two runs are still executing the same code in all threads) and, moreover, the same number of  $lvl_A$ -visible events have been performed so far in  $y$  and  $y'$  and, for all levels  $lvl$ , the same number of inputs from channel  $lvl$  has been consumed in both  $y$  and  $y'$ .*

#### Extensional Policies.

**Definition A.3** (Extensional Delimited Release Policy for Figure 1 and Section 6.1). *For completeness, we specify the extensional security property that the delimited release*

*policy for Figure 1 (see Definition 3.4.5) encodes.*

$$\begin{aligned} & \forall \sigma \text{ sched } y \sigma'. \\ & (\forall n. \forall h \in \{\lambda vs. \text{ if } len(vs) \neq 0 \text{ then } CK(last(vs)) \text{ else } 0, \\ & \quad \lambda vs. \text{ if } len(vs) \neq 0 \wedge CK(last(vs)) = 0 \\ & \quad \text{ then } last(vs) \text{ else } 0\}. \\ & \quad h(\text{take}(n, env_\sigma)) = h(\text{take}(n, env_{\sigma'}))) \wedge \\ & \sigma \stackrel{\perp}{\approx} \sigma' \wedge (ls, \sigma, \text{sched}) \rightarrow^* y \Rightarrow \\ & \exists y'. (ls, \sigma', \text{sched}) \rightarrow^* y' \wedge tr_y \stackrel{\perp}{\approx} tr_{y'} \end{aligned}$$

**Definition A.4** (Extensional Confirmed Declassification Policy for Section 6.2).

$$\begin{aligned} & \forall \sigma \text{ sched } \sigma' \text{ } ls' \text{ } sched' \text{ } ls'' \text{ } \sigma'' \text{ } sched'' \text{ } e. \\ & (ls, \sigma, \text{sched}) \rightarrow^* (ls', \sigma', \text{sched}') \wedge \\ & (ls', \sigma', \text{sched}') \rightarrow^* (ls'', \sigma'', \text{sched}'') \wedge tr_{\sigma''} = tr_{\sigma'} \cdot e \Rightarrow \\ & \begin{cases} v = \text{lastoutput}(\top, \sigma') \wedge & \text{if } e = \mathbf{d}(\perp, v, E) \\ \text{lastinput}(\perp, \sigma') = 1 & \\ \text{uncertainty}_{lvl_A}(ls, \sigma, \text{sched}, tr_{\sigma'}) \subseteq & \text{otherwise} \\ \text{uncertainty}_{lvl_A}(ls, \sigma, \text{sched}, tr_{\sigma'} \cdot e) & \end{cases} \end{aligned}$$

**$lvl_A$ -Bisimilarity.**  $lvl_A$ -bisimilarity is defined via the notion of an  $lvl_A$ -secure bisimulation. Essentially a  $lvl_A$ -secure bisimulation is a relational invariant on the execution of a thread that ensures that each step of its execution satisfies what we call  $lvl_A$ -step security.

**Definition A.5** ( $lvl$ -Step Security). *Let  $lvl$  be a security level. Let  $\sigma$  and  $\sigma_2$  be global states such that a single execution step has occurred from  $\sigma$  to reach  $\sigma_2$ , and let  $\sigma'$  and  $\sigma'_2$  be likewise, such that  $\sigma \stackrel{lvl}{\approx} \sigma'$ . Then these states satisfy  $lvl$ -step security, written  $\text{stepsec}_{lvl}(\sigma, \sigma_2, \sigma', \sigma'_2)$ , iff:*

- *If the execution step from  $\sigma$  produced a declassification event visible at level  $lvl$ , then, whenever the same event is produced by the step from  $\sigma'$ , we require that  $\sigma_2 \stackrel{lvl}{\approx} \sigma'_2$ .*
- *If the execution step from  $\sigma$  produced a declassification event not visible at level  $lvl$ , then we require that  $\sigma_2 \stackrel{lvl}{\approx} \sigma'_2$  unconditionally.*
- *In either case, the number of  $lvl$ -visible events in  $tr_{\sigma_2}$  and  $tr_{\sigma'_2}$  must be equal.*
- *Otherwise, if no declassification event is produced in the step from  $\sigma$ , we require that  $\sigma_2 \stackrel{lvl}{\approx} \sigma'_2$ .*

**Definition A.6** ( $lvl$ -Secure Bisimulation). *For a security level  $lvl$ , a binary relation  $\mathcal{R}$  on thread local states  $(i, c)$  is an  $lvl$ -secure bisimulation iff whenever  $(i, c) \mathcal{R} (i', c')$ :*

- $i = i'$
- $c = \text{stop} \iff c' = \text{stop}$
- *An execution step of  $((i, c), \sigma) \rightsquigarrow ((i, c_2), \sigma_2)$  from a global state  $\sigma$  that satisfies  $c$ ’s annotation, can be matched by a step  $((i, c'), \sigma') \rightsquigarrow ((i, c'_2), \sigma'_2)$  from any global state  $\sigma'$  that satisfies  $c'$ ’s annotation whenever  $\sigma \stackrel{lvl}{\approx} \sigma'$ .*

$$\frac{(ls_i, \sigma) \rightsquigarrow (ls'_i, \sigma')}{(ls_0, \dots, ls_i, \dots, ls_{n-1}, \sigma, i \cdot sched') \rightarrow (ls_0, \dots, ls'_i, \dots, ls_{n-1}, \sigma', sched')} \text{GSTEP}$$

$$\frac{\nexists y. (ls_i, \sigma) \rightsquigarrow y}{(ls_0, \dots, ls_i, \dots, ls_{n-1}, \sigma, i \cdot sched') \rightarrow (ls_0, \dots, ls_i, \dots, ls_{n-1}, \sigma, sched')} \text{GWAIT}$$

Figure 7: Concurrent execution. Here,  $\cdot \rightsquigarrow \cdot$  is the small-step semantics of individual thread programs (see Figure 8).

$$\frac{[E]_{mem_\sigma} = v \quad mem' = mem_\sigma[x \mapsto v]}{((i, \{A\}x := E), (env_\sigma, mem_\sigma, locks_\sigma, tr_\sigma)) \rightsquigarrow ((i, \mathbf{stop}), (env_\sigma, mem', locks_\sigma, tr_\sigma))} \text{ASSIGN}$$

$$\frac{[E]_{mem_\sigma} = v \quad mem' = mem_\sigma[x \mapsto v] \quad tr' = tr_\sigma \cdot \mathbf{d}\langle \mathcal{L}(x), v, E \rangle}{((i, \{A\}x \widehat{=} E), (env_\sigma, mem_\sigma, locks_\sigma, tr_\sigma)) \rightsquigarrow ((i, \mathbf{stop}), (env_\sigma, mem', locks_\sigma, tr'))} \text{DASSIGN}$$

$$\frac{[E]_{mem_\sigma} = v \quad tr' = tr_\sigma \cdot \mathbf{out}\langle lwl, v, E \rangle}{((i, \{A\}lwl ! E), (env_\sigma, mem_\sigma, locks_\sigma, tr_\sigma)) \rightsquigarrow ((i, \mathbf{stop}), (env_\sigma, mem_\sigma, locks_\sigma, tr'))} \text{OUTPUT}$$

$$\frac{[E]_{mem_\sigma} = v \quad tr' = tr_\sigma \cdot \mathbf{d}\langle lwl, v, E \rangle}{((i, \{A\}lwl \widehat{=} E), (env_\sigma, mem_\sigma, locks_\sigma, tr_\sigma)) \rightsquigarrow ((i, \mathbf{stop}), (env_\sigma, mem_\sigma, locks_\sigma, tr'))} \text{DOUTPUT}$$

$$\frac{env_\sigma(lwl) = v \cdot vs \quad env' = env_\sigma[lwl \mapsto vs] \quad mem' = mem_\sigma[x \mapsto v] \quad tr' = tr_\sigma \cdot \mathbf{in}\langle lwl, v \rangle}{((i, \{A\}lwl \leftarrow v), (env_\sigma, mem_\sigma, locks_\sigma, tr_\sigma)) \rightsquigarrow ((i, \mathbf{stop}), (env', mem', locks_\sigma, tr'))} \text{INPUT}$$

$$\frac{[E]_{mem_\sigma} = \mathbf{true}}{((i, \{A\}\mathbf{if} E c_1 \mathbf{else} c_2 \mathbf{endif}), \sigma) \rightsquigarrow ((i, c_1), \sigma)} \text{IFT} \quad \frac{[E]_{mem_\sigma} \neq \mathbf{true}}{((i, \{A\}\mathbf{if} E c_1 \mathbf{else} c_2 \mathbf{endif}), \sigma) \rightsquigarrow ((i, c_2), \sigma)} \text{IFF}$$

$$\frac{((i, c_1), \sigma) \rightsquigarrow ((i, c'_1), \sigma') \quad c'_1 \neq \mathbf{stop}}{((i, c_1; c_2), \sigma) \rightsquigarrow ((i, c'_1; c_2), \sigma')} \text{SEQ} \quad \frac{((i, c_1), \sigma) \rightsquigarrow ((i, c'_1), \sigma') \quad c'_1 = \mathbf{stop}}{((i, c_1; c_2), \sigma) \rightsquigarrow ((i, c_2), \sigma')} \text{SEQSTOP}$$

$$\frac{[E]_{mem_\sigma} = \mathbf{true}}{((i, \{A\}\mathbf{while} E \mathbf{inv}\{I\}\mathbf{do} c), \sigma) \rightsquigarrow ((i, c; \{A\}\mathbf{while} E \mathbf{inv}\{I\}\mathbf{do} c), \sigma)} \text{WHILET}$$

$$\frac{[E]_{mem_\sigma} \neq \mathbf{true}}{((i, \{A\}\mathbf{while} E \mathbf{inv}\{I\}\mathbf{do} c), \sigma) \rightsquigarrow ((i, \mathbf{stop}), \sigma)} \text{WHILEF}$$

$$\frac{locks_\sigma(\ell) \text{ is undefined} \quad locks' = locks_\sigma[\ell \mapsto i]}{((i, \{A\}\mathbf{acquire}(\ell)), (env_\sigma, mem_\sigma, locks_\sigma, tr_\sigma)) \rightsquigarrow ((i, \mathbf{stop}), (env_\sigma, mem_\sigma, locks', tr_\sigma))} \text{ACQUIRE}$$

$$\frac{locks_\sigma(\ell) = i \quad locks' = locks_\sigma[\ell \text{ is undefined}]}{((i, \{A\}\mathbf{release}(\ell)), (env_\sigma, mem_\sigma, locks_\sigma, tr_\sigma)) \rightsquigarrow ((i, \mathbf{stop}), (env_\sigma, mem_\sigma, locks', tr_\sigma))} \text{RELEASE}$$

Figure 8: Semantics of threads, where  $\sigma = (env_\sigma, mem_\sigma, locks_\sigma, tr_\sigma)$ .

Moreover, in that case  $(i, c_2) \mathcal{R} (i, c'_2)$  is preserved and *lwl-step security* is satisfied:  $\text{stepsec}_{\text{lwl}}(\sigma, \sigma_2, \sigma', \sigma'_2)$ .

**Definition A.7** (*lwl-Bisimilarity*). We say that two local thread states  $(i, c)$  and  $(i', c')$  are *lwl-bisimilar*, written  $(i, c) \stackrel{\text{lwl}}{\sim} (i', c')$  whenever there exists a *lwl-secure bisimulation*  $\mathcal{R}$  that relates them:  $(i, c) \mathcal{R} (i', c')$ .

## 2. COVERN-Comparison System

```

1  {A50} acquire( $\ell$ );
2  {A51}  $inmode := inmode + 1$ ;
3  {A52}  $outmode := inmode$ ;
4  {A53} release( $\ell$ ) ;
5  {A54}  $GHOST := 0$ 
      (a) Toggling thread.

1  {A55}  $\top ! \top buf$ 
      (b) Outputting  $\top$  data.

1  {A56} acquire( $\ell$ );
2  {A57} if  $inmode = 0$ 
3    {A58}  $buf \leftarrow \perp$ 
4  else
5    {A59}  $buf \leftarrow \top$ 
6  endif;
7  {A60}  $GHOST := 1$ ;
8  {A61} release( $\ell$ )
      (c) Reading data into a shared buffer.

1  {A62}  $\perp ! \perp buf$ 
      (d) Outputting  $\perp$  data.

1  {A63} acquire( $\ell$ );
2  {A64} if  $outmode = 0$ 
3    {A65}  $\perp buf := buf$ 
4  else
5    {A66}  $\top buf := buf$ 
6  endif ;
7  {A67} release( $\ell$ )
      (e) Copying data from a shared buffer.

```

Figure 9: Co-operative Use of a Shared Buffer without declassification. The variable *GHOST* is a *ghost variable* needed to verify this system in VERONICA but not in COVERN. Specifically, it distinguishes the cases in which *buf* is newly cleared by the toggle thread (Figure 9a) and those in which the reading thread (Figure 9c) has overwritten *buf*: these two cases do not need to be distinguished when using a relational invariant to describe *buf*'s (value-dependent) sensitivity in COVERN, but this distinction is required when encoding this same information via the VERONICA annotations.
